“I feel happy to see this photo. These children didn’t refuse when I asked if I could take a picture of them. It made me laugh, which does me good.”

About the Artist

Cecilia lives with her grandmother and older brother; their parents died of AIDS when Cecilia was very young. Her brother, Serge, runs a small business, providing the family with some income. Contributions from Reencontro, a local NGO, also help make ends meet.

Cecilia loves school. She walks 30 minutes each way to school every day and hopes to be a director of a school when she grows up. Many of her concerns are with her family and home because the roof of the house leaks when it rains and she worries about her grandmother’s health.

WORKFORCE CAPACITY

1 Estimating Health Workforce Needs for Antiretroviral Therapy
Andrew M. Fullem and Lisa R. Hirschhorn

9 Sidebar: Task Shifting in Botswana: Equipping Nurses to Manage and Dispense Antiretroviral Drugs
Joyce Kgatlwane

13 Overcoming Human-Resources-for-Health Challenges at the Service Delivery Level
Stephen N. Kinoti and Nigel Livesley

23 Sidebar: Task Shifting Guidelines in the Era of HIV Program Expansion
Francesca Celletti, Badara Samb, Anna Francesca Wright, Alan Greenberg, and Joan Holloway

31 Caring for Caregivers: Lessons Learned in Addressing the Needs of Health-Care Workers Affected by HIV/AIDS
Michael Vitols, Dorothy Gillian Ngoma, Olive Ngandu, and Isaac Sulwe
37 Popular Training Methodologies and Applications
Elizabeth McCarthy, Anne Sliney, and Megan O’Brien

42 Sidebar: The Development and Application of a Distance Learning Tool for HIV Care and Treatment
Fransje van der Waals

55 Curriculum Development and Training for Comprehensive HIV Care
Kimberly Zeller

73 Sidebar: Training and Treating at the Same Time: Experiences with National HIV/AIDS Training in Nigeria
James C. Shepherd, Abdulrazaq Habib, and Patrick Dakum

77 Supporting National ART Scale-Up in Botswana through Standardized, Multiphased Training

93 Development and Implementation of Training Packages for PMTCT and Pediatric HIV Care
Linda S. Podhurst, Mary Jo Hoyt, Farai Dube, Nomfundo Nhlapo, Lucy Connell, and Robert Ayisi

115 Training and Clinical Mentorship to Support the Scale-Up of Pediatric HIV Care: Lessons Learned from Uganda
Edward Bitarakwate

125 Developing National Training Materials for Prevention of Mother-to-Child Transmission of HIV: The Zimbabwe Experience
Agnes Mahomva, Anna Miller, and Rumbidzai Mugwagwa

137 Expanding the Role of Nurses and Advanced Practice Nursing in HIV/AIDS Care
Suzanne Willard

142 Sidebar: The UCSF ASPIRE Nurse Training Program
By Catherine Lyons, Project ASPIRE, University of California, San Francisco

144 Sidebar: Experiences and Challenges among Nurses in Malawi
By Evelyn B. Chilemba, Kamuzu College of Nursing, University of Malawi
LABORATORY AND PHARMACY SERVICES

153 Challenges in Developing Laboratory Capacity and Infrastructure to Support HIV/AIDS Care Programs
John N. Nkengasong, Deborah Birx, and Jean-Louis Sankalé

177 Developing Laboratories to Support HIV-Related Service and Research Activities in Sub-Saharan Africa
Wendy Stevens and Deborah K. Glencross

189 Managing Medicines and Supplies for HIV/AIDS Program Scale-Up
Helena Walkowiak and Douglas Keene

209 HIV/AIDS Drug Procurement and Supply Chain Management
Yasmin Chandani, Eric Takang, Claudia Allers, and Colleen McLaughlin

231 Lower-Cost Laboratory Monitoring for CD4 T-Lymphocyte Enumeration, HIV RNA Quantitation, and Drug Resistance
Seble Kassaye, Cybele Renault, and Dennis M. Israelski

249 Expanding the Role of Pharmacy Staff in Antiretroviral Therapy
Helena Walkowiak and Douglas Keene

MONITORING, EVALUATION, AND QUALITY OF CARE

261 The Third One: Monitoring and Evaluation of HIV Programs
John Puvimanasinghe, Wayne Gill and Eduard Beck

293 The Third One in Practice: Monitoring and Evaluation of the Botswana National HIV Response
John Puvimanasinghe, Wayne Gill and Eduard Beck

307 The Importance of Standard Operating Procedures for HIV Care
Leine Stuart, Eric van Praag, Babajide Keshinro, and Mukadi Ya Diul

317 Quality Management in HIV Care
Lisa R. Hirschhorn and Bruce D. Agins

331 Achieving and Maintaining Quality in HIV Care: Lessons Learned from Zambia
Mary Morris and Nicole M. Quiterio
HUMAN RIGHTS AND HIV CARE

343 Universal Access: Are National Strategic Plans Sensitive to Human Rights?
Daniel Tarantola and Sofia Gruskin

363 Human Rights and Women’s Empowerment in the Context of HIV and AIDS
Eka Esu-Williams

379 Overcoming Obstacles to Care and Treatment for Women Living with HIV
Deloris Dockrey and Lynde Francis

386 Sidebar: Transforming Male Gender Norms to Address the Root Causes of HIV and AIDS
Andrew Levack

391 Adopting Human Rights Standards in the Scale-Up of HIV/AIDS Care: Lessons Learned from Argentina, Botswana, and Thailand
Shyami Puvimanasinghe, Christine Stegling, Karyn Kaplan, Mabel Bianco, and Paisan Suwannawong

401 HIV Care, Treatment, and Prevention in Conflict Settings
Susan Purdin, Wendy Venter, and Roxanne Saucier

413 Barriers to HIV/AIDS Prevention, Care, and Treatment for Men Who Have Sex with Men
Vasu Reddy and Theo Sandfort

422 Leadership Profile: Noerine Kaleeba
HE END OF AIDS IS STILL NOWHERE IN SIGHT. Every day, almost three times as many people become newly infected with HIV as those who start taking antiretroviral treatment. Now that we are well into the new millennium, the HIV/AIDS response must also enter a new phase, a phase that combines continuing crisis management with a long-term, sustainable response.

One of the main lessons we have learned through the experience in recent years of providing antiretroviral therapy to millions of people is that we should not wait until systems are fixed before acting. Getting three million people on antiretroviral therapy is an achievement that would have been unthinkable back in 1999. Yet if we had continued to wait, if we had listened to those who said it couldn’t be done, the majority of these three million people would no longer be with us.

Our efforts thus far, while far from perfect, are proof that great progress can be made when dedicated people in all parts of the world join together to do the best they possibly can despite limited financial and human resources. The chapters contained in the three volumes of *From the Ground Up*, while representing only a small fraction of these efforts, are a testament to this unyielding will, and the immense amount of experience that has been accumulated in this relatively new field.

Yet great progress cannot be achieved in isolation. We in the AIDS movement must forge more concrete linkages with those working to improve health systems generally, so that we can achieve maximum benefits all around. We will need to work across sectors to achieve the massive scale-up of efforts that is required—that is why this text covers not only the direct provision of prevention, care, and treatment services, but a myriad of related issues that must be considered if the care that we do deliver is to be of the highest quality. By the same token, the AIDS response cannot be disconnected from overall development efforts, or from other health activities, such as TB and reproductive, maternal, and child health.

Getting the “how” as well as the “what” of implementation right is critical to reaching our collective goal of stopping this pandemic. *From the Ground Up* is part of a rapidly growing movement to collect and disseminate the best practices and lessons learned from our monumental efforts over the last quarter century. We must continue to find new and better ways of harnessing this critical information to quicken the pace of progress and avoid duplication of efforts. We are at the point where we must start to think—and implement—in new ways. But one thing will not change: the only way we will ever succeed is by working together.

Peter Piot

*Peter Piot, M.D., Ph.D. served as executive director of the Joint United Nations Programme on HIV/AIDS (UNAIDS) from the agency’s creation in 1995 until the end of 2008. He currently serves as a professor and director of the Global Health Institute at Imperial College London and is a senior fellow at the Bill & Melinda Gates Foundation (2009) and scholar in residence at the Ford Foundation (2009).*
Preface

The title of this publication, From the Ground Up, reflects our desire to establish a new paradigm for sharing the enormous wealth of information stemming from over 20 years of HIV/AIDS program implementation experience. By reversing the typical “top-down” flow of information, the voices of hundreds of talented professionals on the front lines of the HIV/AIDS response can now be heard by all those who stand to benefit, regardless of their geographic location or position within the vast network of institutions and individuals that comprise the global HIV/AIDS community. While the Elizabeth Glaser Pediatric AIDS Foundation has served as the publisher of this text, the methods by which the content was developed are characterized by a remarkable level of collaboration involving hundreds of individuals and their affiliated institutions. A total of over 320 individuals contributed to these three volumes, generously volunteering their time to document an array of efforts in all aspects of HIV care, treatment, and prevention, as well as a host of related issues that constitute a truly comprehensive response to HIV and AIDS.

Comprehensive HIV/AIDS care is defined here as all approaches that hold the potential to enhance the health and well-being of people living with and affected by HIV and AIDS. Yet it must be recognized that it would be impossible for any single publication, no matter how large, to contain an exhaustive review of all efforts constituting an effective HIV/AIDS response. In fact, despite the large quantity of information gathered within these pages, they contain a mere snapshot of the multitude of impressive efforts underway in sub-Saharan Africa and elsewhere. We hope that this text, despite its limitations, will serve as a significant milestone along the multiple, simultaneous but often distinctive paths that are leading us out of the current crisis and toward a new era of long-term, strategic, and informed approaches to HIV/AIDS program implementation in resource-limited settings. We can learn a great deal from one another, and the information gathered here brings us a small step closer to achieving the level of knowledge sharing required to further the pace of progress in every aspect of our work.

Readers will quickly notice that the Foundation’s programs are not the focus of this text; rather, the Foundation’s work is profiled alongside that of more than 140 respected public health institutions around the world. This is in recognition of the fact that the global response comprises a multitude of individual efforts and experiences and is greatly enriched by a diverse array of practical and philosophical approaches. We have also made a concerted effort to reflect the Foundation’s specific focus on women and children throughout this publication. In accordance with the Foundation’s mission “to prevent pediatric HIV infection and to eradicate pediatric AIDS through research, advocacy, and prevention and treatment programs,” several chapters have been devoted to the care of women and children living with and affected by HIV and AIDS. In addition, each author has been asked to consider the special care needs of women and children in the context of their chosen topic in an effort to urge us all to be as inclusive and strategic as possible in addressing the needs of these particularly vulnerable groups.

The three volumes of From the Ground Up are named and organized according to the key stages of comprehensive HIV/AIDS program implementation. Each volume opens with an introduction by a recognized leader in the HIV/AIDS field, framing the chapters that follow in the context of the author’s
own vast professional experience. Bookending the regular chapters of each volume, readers will find full-color profiles of remarkable individuals on the front lines of the HIV/AIDS response. These true heroes embody the unyielding devotion to their work and tireless spirit that characterize so many in our field, and we are proud to be able to highlight their remarkable contributions within these pages to inspire and uplift us all.

The chapters contained in the first of these three volumes, “Laying a Strong Foundation,” emphasize the importance of ensuring that a range of critical program components, from workforce capacity to human rights, are in place before embarking on service provision. Such considerations are critical to the success of any comprehensive program, and as such should always be made at the outset of program planning and implementation. The chapters contained in the second volume, “Establishing a Framework for Success,” remind us that the creation of a strong foundation, while critically important, is only the first step. We must then establish a framework of proven strategies, based on the best available scientific evidence, which will guide us in every aspect of our work. The chapters in the third and final volume, “Building Pathways and Partnerships,” show us that once programs are established, the human networks that provide access to and enhancement of the services provided are critical to their ultimate success. Only by ensuring that programs are appropriately linked with the populations they serve and are working in concert with complementary community-based efforts, can we be confident that services will reach those who need them most.

Finally, we wish to point out that this text is not meant to serve as a definitive guide to program implementation. As we are all aware, there is no magic formula that, if followed to the letter, will yield a perfect HIV/AIDS program. Rather, From the Ground Up contains a number of different viewpoints for the benefit and enrichment of the reader, some of which may reflect differing perspectives on a given issue, and some of which may not be applicable in a given setting. As such, we encourage readers to apply the knowledge and experience documented within these pages at their discretion, just as we encourage all those in this dynamic field to never cease building and improving upon their own work and that of their colleagues. As implementers, we all are in the process of “learning by doing,” but we must not forget that it is equally, if not more important, to “learn by listening” to our venerable colleagues and the communities we serve around the globe.

Richard G. Marlink
Sara J. Teitelman
Introduction

SINCE THE FIRST CASES OF INFECTION with what became known as HIV were reported in 1981, the AIDS pandemic has grown into one of the most devastating public health threats of our time. The Elizabeth Glaser Pediatric AIDS Foundation is proud of its efforts over the last two decades, growing from a small domestic organization to a worldwide leader in the fight against pediatric HIV and AIDS. And while our work and the work of our colleagues is far from over, it is important to reflect on what has been accomplished to date and the challenges that lie ahead as we move toward creating a generation free of HIV. In this spirit, the Foundation is proud to have led the creation of From the Ground Up, a landmark effort to compile valuable insights and experiences from a wide array of HIV/AIDS professionals working in resource-limited settings.

Many remarkable achievements have been made in the HIV/AIDS field since the virus was first discovered, from scientific advances to the breaking down of political and social barriers. Of particular importance, the wider availability of more effective, less costly treatments has begun to convert HIV infection from a death sentence into a chronic, manageable disease. These developments have led to the roll-out of antiretroviral therapy programs in even the most resource-limited settings, which are now delivering life-saving treatments and essential care and prevention services to millions of people. Such rapid progress has been made possible in part by historic increases in funding for international HIV/AIDS care, treatment, and prevention programs.

We have come a long way, but much more remains to be done. In the hardest hit regions of the world, where both financial and human resources for health are in short supply, HIV and AIDS remain formidable threats to the health and well-being of millions of people. In 2007, an estimated 33 million people were living with HIV, up from 29 million in 2001. At the end of that year, some 2.7 million people, 370,000 of whom were children, had been newly infected with the virus, and an estimated 2 million people had died of AIDS-related illnesses. Sub-Saharan Africa remains the most affected region in the world, and is home to more than two-thirds of all people living with HIV, the majority of whom are women. In response, the Foundation is working hard to address the health needs of affected women and their families in the 18 countries where we work.

As we enter a new era characterized by the wider availability of antiretroviral therapy, we must remember that treatment and prevention go hand in hand. We will only be doing half of what is required to bring the epidemic under control unless we can stem the tide of new infections. Promising steps are being taken in this regard: By the end of 2007, 34% of HIV-positive pregnant women globally received the medicines they needed to prevent transmission of HIV to their babies, up from 14% in 2005. Much of that increase came from the expansion of services in low- and middle-income countries. The Foundation is doing its part to ensure expanded access to both prevention and treatment services. As of December 2008, we have provided more than 6.6 million women with services to prevent the mother-to-child transmission of HIV and have enrolled more than 620,000 people, including more than 50,000 children, in HIV care and treatment services. But there is still much to be done. At the end of 2007, just 31% of the 9.7 million people in need of antiretroviral treatment worldwide were receiving it.
Given the urgency and complexity of our work, we rarely have an opportunity to stop and consider what lessons can be culled from our own experiences, let alone those of others. Yet learning from one another is precisely what is needed to quicken the pace of progress and ensure that the experiences of the past serve to strengthen future efforts. *From the Ground Up* is a testament to the importance of working together, highlighting how greater collaboration and communication can enable those working on the front lines to mount new and more effective responses to the HIV/AIDS crisis.

*From the Ground Up* is not a “how-to” manual. Rather, it is a collection of many different viewpoints and experiences, each as unique as its authors. The Foundation spearheaded this important project not only to broaden our own base of knowledge about the current state of HIV/AIDS program implementation, but also to encourage the application of these lessons by others in our field. As you begin to explore these three volumes, you will find that the chapters have been written by a group of more than 320 HIV/AIDS professionals working in a variety of resource-limited settings and representing a multitude of institutions—ranging from large international consortiums and national governments to community-based organizations. These diverse professionals have shared their experience and expertise on a wide variety of topics, from workforce capacity and human rights to HIV medicine and community-based care. Each informative and thought-provoking chapter forms part of a rich and colorful mosaic of the wide variety of efforts currently underway around the globe.

We hope you enjoy reading and using this text as much as we have enjoyed assembling it. While the road ahead is sure to be challenging, learning from the experiences of our colleagues can help us to end the AIDS pandemic—and create a generation free of HIV.

MARA BANDA WITH MIRACLE, THE BOY THAT SHE SAVED FROM BEING KILLED BY HIS FAMILY AFTER BOTH HIS PARENTS DIED FROM AIDS
Mara Banda

Director of Paradiso Community Health Project, Malawi

MARA KUMBWEZA BANDA’S life had always been full of turmoil. When she was a girl, her father was suddenly fired from his job as a minister in the Malawian government, and the family lost their house and all the belongings inside. As a young mother of four boys, her husband died in a traffic accident. And then in 2000, Banda learned she was HIV-positive.

In those days in the Ngwenya Township southwest of Lilongwe, she remembers, people all around her were dying from AIDS. “We used to have six funerals a day. People died as couples. The wife would die in the morning and the husband would die in the evening,” she said.

It was one such tragedy that changed Banda’s life. One day in 2002, a woman in her community died giving birth. Her baby boy survived. But a week later, the father died as well, and the family decided quietly that they were going to kill the boy, believing he was a witch.

Banda, knowing AIDS had killed the couple, stepped in. “I said, ‘You can’t kill him, he’s innocent. Let’s keep the baby. We’ll help.’”
People brought clothes and food, and Banda found women to nurse the baby. The baby lived.

That started her on a project to look after the sick and the children in her community. She founded Paradiso House and Home-Based Care in a building donated by community leaders. It sits on the side of a stone mountain, where local people slowly chip away at the rocks, crushing rock piles into stone, and sell their labors for $1 a day to construction companies.

In just a few years, her project has taken off. Twenty volunteer home-based workers check in on a total of 300 people in their homes a few times a week. She has registered 264 orphans, feeding them twice a week and supporting 70 with school fees. And in 2007 she did it on just $13,000—by far her biggest budget yet. The donations come from Americans, Scots, Norwegians, and many Malawians.

The advent of free antiretroviral treatment and the greater acceptance of people getting tested for HIV has dramatically changed the work around AIDS, she said. But the community also has greatly benefited from Banda’s vision.

“She didn’t want to just help herself,” said Georgina Msito, 24, Banda’s niece, who now volunteers at Paradiso. “She has got a heart for others.”

So for Banda, 48, a life’s worth of turmoil has abated, for the time being. She has her health. She has the support of her four boys. She dances and sings with her volunteers nearly every week outside her building, their feet raising dust and their voices rising above the sounds of makeshift hammers striking stones in the hill above.

And she has that boy whom she helped save one night not so long ago. Sitting in a meeting room at Paradiso, she asked her youngest son to go find him. He returned a few moments later with a boy who had round checks and a dazzling smile.

“This is that boy—that boy we saved,” Banda said, as the boy climbed onto her lap and nestled in her arms. “We call him Miracle.”
Q: When was the moment that you felt you were committed to this work?
“When we got the building in 2003. I cried. I still cry when I think about it. [She starts to weep.] It’s so emotional. It was exciting. People had acknowledged my work. My work would grow. I would have a place of my own. I cried the whole night, the whole next day. I came in that morning to sweep. Everybody was so excited. Everybody was crying.”

Q: When did you realize that working on AIDS would be so consuming?
“When the community started catching on to the work we were doing, it dawned on me that maybe I will have to do this work my entire life. It is so much better today than it was just a few years ago, when people were knocking on my door at all hours, people were dying every day. But I still have to put all my effort into this. I am starting to look at the future of the program. If God keeps me alive into my 80s, maybe—maybe—I won’t be able to do all this work then” [laughs].

Q: How will you sustain Paradiso?
“We are doing a lot of outreach to the youth. It’s the old way of elders handing down information. It isn’t anything written down. It is young people watching elders do things. And we in turn are observing and encouraging the youth so they can fully develop. This youth team will bring this disease down. The youth have gotten really frightened about HIV and AIDS. They say they are not going to make any silly mistakes. They are going in for testing and counseling. And we have very few HIV-positive youth here.”

Q: What will be the biggest challenges in the years ahead?
“There’s a very weak link between the health sector and the donors with the community-based organizations. A lot of big umbrella organizations get funding from the Global Fund or PEPFAR [President’s Emergency Plan for AIDS Relief]. But the funding often stays in those organizations, the big institutions. It’s very difficult for groups like ours to access funding.

“The other big challenge is that we need to start income-generating activities. Paradiso is drifting into a donor-dependency situation. We’re not doing something to sustain us. This should be our main focus ahead—to start a project that will sustain us without outside funds. We need to have a good capital base.”
Introduction to Volume I: Laying a Strong Foundation

As HIV/AIDS professionals, we go to work every day with a sense of great urgency. The services we provide can literally mean the difference between life and death for millions of individuals. Yet while there will always be a temptation to rush into service provision given the overwhelming demand that exists, HIV/AIDS services must be built upon a strong foundation, consisting of a capable workforce, sound laboratory and pharmacy infrastructure, appropriate monitoring and evaluation strategies, and a commitment to upholding human rights principles in all that we do.

In 1998, the Joint United Nations Program on HIV/AIDS (UNAIDS) and the World Health Organization (WHO) issued guidelines concerning the “minimum requirements” for the provision of safe and effective antiretroviral therapy. These included: laboratory facilities to monitor adverse reactions, appropriate training for clinicians and nurses in the correct usage of antiretroviral drugs, social support networks, and reliable drug supplies. The sections contained in this first of the three volumes of From the Ground Up closely mirror these original key requirements, which remain the cornerstones of quality HIV care and treatment today. In addition, and reflective of the social support requirement mentioned by WHO and UNAIDS at that time, the final section of this volume emphasizes that programs must operate in accordance with basic human rights principles, and that we as HIV/AIDS professionals must work to respect and uphold the basic human rights of the individuals and groups we serve.

Without these basic building blocks, programs risk failure and in some cases, may end up doing more harm than good. But while these building blocks are all essential ingredients, there are a variety of different viewpoints and approaches to fulfilling these requirements, a portion of which are reflected in the chapters contained in the following sections. In the “Workforce Capacity” section, we will learn how to estimate workforce needs, while other chapters will guide us in how to retain and strengthen this workforce once it has been assembled. In the “Laboratory and Pharmacy Services” section, we will learn of some of the key challenges facing programs given the increased availability of antiretroviral therapy and other services, and how lack of laboratory capacity can serve as a debilitating bottleneck if not properly managed in concert with other scale-up activities. We will also see how innovative approaches to lower-cost laboratory monitoring, as well as expanded roles for pharmacy staff, can help overcome some of these significant challenges.

In the “Monitoring, Evaluation, and Quality Management” section, the authors provide us with a “big picture” of the key principles of monitoring and evaluation, as well as how these are being put into practice in novel and interesting ways that reflect the additional technological tools we have at our disposal in the 21st century. We will also learn how to ensure the quality of our programs through quality management, a powerful tool for enhancing patient care, maximizing resources, and improving workforce morale. And finally, in the “Human Rights and HIV Care” section, we learn how several national HIV/AIDS programs are performing in terms of their stated commitment to human rights, as well as some the key challenges in reaching the most vulnerable groups, such as women and men who have sex with men.
While the international HIV/AIDS response is an ever-changing mosaic of initiatives, affected populations, and social issues, many things remain constant. Among these constants are the cornerstones of good service provision mentioned earlier. Another constant is the opportunity we all have to use our work in HIV/AIDS as an avenue for addressing the broader iniquities and stigma that afflict so many modern societies. As you read through the chapters that follow, I urge you to take a moment to imagine a future in which all health programs, whether for HIV/AIDS or other grave public health threats, are built upon these cornerstones of quality service provision, and how such a reality could bring us closer to reaching the ambitious yet imperative goals we have set for ourselves to transform societies for the benefit of all, and especially for historically underserved populations.

Shelia Tlou

Shelia Tlou, MSN, Ph.D., is the former Minister of Health for Botswana (2004 to 2008) and a professor of nursing. Dr. Tlou has also served as the AIDS coordinator for the University of Botswana since the inception of the position. Her work continues to focus on raising public awareness of issues related to HIV/AIDS, women’s health, gender, and human development.
Daniel Onayi in front of one of his rock paintings that states “say no to AIDS”
LARGE, MAJESTIC BOULDERS line either side of the rutted dirt road that passes through the village of Ibwona in western Kenya. Villagers often climb to the top of those easily scalable rocks to see the world from a different height. But Daniel Ongayi saw the boulders serving another purpose—as his own personal canvas.

A canvas of rock to fight AIDS.

In white paint, he wrote messages on the boulders lining over a mile of road: “Stress is a Killer,” “AIDS has entered into the beds like bedbugs,” “Give HIV-Positive Person an Opportunity, not Sympathy,” and “Girls: Avoid Vitamin M”—M standing for the money older men give girls for sexual favors.

He drew animals as well: hippos, giraffes, crocodiles, and birds. On several of the boulders, he signed his work, boldly and with a hint of humor:
“I panicked. I felt my whole family would die. I built a
to my self, my wife, and our five children.”

“By Dan-HIV Man.”

Then, to make sure people would have no trou-
ble finding him, he painted his cell phone number
on boulder after boulder.

“I did it because people should be aware that
AIDS is all around them,” Ongayi said on one recent
afternoon by his boulders. “I did it so that people
wouldn’t be afraid to tell others about their status.”

He stood among the boulders at a local gathering
spot. More than a dozen villagers sat on the huge
rocks, waiting for taxi vans. One by one, people
walked by on a path that leads to one section of the
village and on into a forested area. A few walked over
to him to say hello. Some said he had affected the
lives of everyone in the village, which has an estimated
population of 20,000. In the AIDS world, the village
has become a rare place where most people not only
know their status but are not afraid to talk about it.

“At first, people looked at him like he was not
normal,” said Haddah Otwoma, 26, a university
student majoring in information science. “But we
found out that he’s OK. Because of him, people are
coming out and talking about their status. It’s a very
good thing.”

Ongayi walked over to show the drawings of ani-
mals on the rocks. Each, he said, has a meaning.

The hippo: “It’s a huge animal that stays under-
water, in mud, during the day. It walks out only at
night, the better to hide itself—just like a person
with AIDS who hides their status.”

The giraffe: “It is tall and brave. When you use
ARVs [antiretroviral medicine], you slowly stand
on your feet again. ARVs make you stand tall like
a giraffe.”

The skull of a crocodile: “It means if you play
with AIDS, it will not spare you. Just like if you go
into the water, the crocodile will eat you.”

Ongayi, 47, the father of five children, first
tested positive for HIV in 1994. He hasn’t limited
his AIDS work to boulder art. He also helped form
the ANDEKA Association, a support group for men
infected with the virus.

Two of his friends hopped out of a taxi van. “This
one is positive living,” Ongayi said. “And that one
with the white cap, he is positive living, too.”

Harrison Omuka, 52, the man in the white cap,
greeted him. “We are free,” he said. “It is not a big
deal to say you’re positive—not in this village. By
coming out, it’s a kind of medicine of its own. You
don’t have to hide.”
Q: Was it always so easy for you to talk about your HIV status?
What happened after you learned you had HIV?
“I was a driver. You know how drivers act. I had a girlfriend in another place. My girlfriend, it turns out, was positive. So I caught the disease. When I told my wife, she wanted to leave me. But she just prayed to God and found peace. I was very fortunate. She decided not to leave me.”

Q: How did the rest of your family react?
“I remember that my mother cooked some tea for me. I told her and the rest of my family. And after I finished the tea, my brother took the cup I was using and threw it into the pit latrine. I started feeling I could die at any moment. I panicked. I felt my whole family would die. I built a huge grave by the side of my house—big enough for myself, my wife, and our five children. I also decided they shouldn’t spend money on my coffin, that I should build my own. I did that. I built it and I put it under the bed.”

Q: You slept over your coffin?
“For six years.”

Q: Then what happened?
“I started on ARVs. It was 2002. My CD4 count was 140. I improved almost immediately, and I destroyed the coffin.”

Q: How did people react to you initially when you starting writing and drawing on the boulders?
“Most of the people here said that I was using witchcraft. That I was a witch. But I told them, ‘No, we are trying to disseminate practical information about AIDS.’ I told them that if I could do this writing on stones, I would be trying to call people together. I would be using common sense—let people know about the disease, tell everyone that it’s OK to say you have it.”

Q: What will be the biggest challenges for people living with HIV in the years ahead?
“The medicine is there for us now. But more and more people will need basic things—food, shelter, access to water, money for transport. Right now, I myself cannot send two of my children to secondary school because I do not have the money for school fees. Sometimes I get really depressed—not because of my HIV status, but because it’s so hard to earn a living.”
WORKFORCE CAPACITY
HEALTH-CARE FACILITIES IN RESOURCE-limited settings have long faced chronic shortages of appropriately trained staff. The World Health Organization (WHO) estimates that there are currently more than 39 million health service providers worldwide. Yet sub-Saharan Africa, home to nearly one-quarter of the world’s disease burden, retains only 3% of the global health workforce. Despite the significant unmet workforce need in many countries in the region, 25% of physicians and 20% of nurses trained in Africa currently work in high-income, Organization for Economic Co-operation and Development (OECD) countries. Although this phenomenon is not new and has been widely reported, the HIV epidemic and the recent focus on expanding HIV clinical care programs only serve to heighten awareness of and concern for this issue. The complex nature of implementing and sustaining quality HIV care—in particular, providing antiretroviral therapy (ART)—requires a team of well-trained clinical staff, auxiliary health personnel, and nonclinical staff. Health-care systems in resource-limited countries are overburdened and understaffed and face competing demands for the same staff. In light of this situation, the public-health system, especially HIV treatment programs, is finding that one of the greatest obstacles to rapid expansion of ART programs is the shortage of human resources. Unless immediate attention is paid to this critical need, we may find ourselves in a situation referred to as “medicines without doctors.”

GENERAL FACTORS THAT INFLUENCE WORKFORCE DEPLOYMENT

A number of often interrelated factors impact the ability of facilities, programs, and national health authorities to adequately address the staffing needs of HIV clinical care programs. Some influences are common across the health-care system, while others are specific to HIV. Some internal and external factors include the following:

- **Emigration.** Given the relatively low salary levels in most resource-limited countries, physicians and nurses opt to leave their homes for more lucrative opportunities in countries that have higher compensation levels.

- **Decline in life expectancy.** The health sector keenly feels the economic impact of HIV. With lower life expectancy in many of the
countries most heavily affected by HIV, countries must address a shrinking workforce due to mortality.3

- **HIV-related absenteeism.** In many countries that are severely affected by HIV, there is significant lost work productivity due to individuals who are absent from work in order to tend to their own HIV clinical care needs or illnesses, to care for a family member living with HIV, to attend to the needs of orphans and vulnerable children who have joined the family, or to participate in funerals. This often unplanned time away from work complicates routine provision of clinical and support services.

- **Migration to the private sector.** In many countries, there is an increased migration of qualified clinical personnel from the public to the private sector. The reasons for this internal migration are numerous, but include relatively better salary and compensation levels in the private sector, better working conditions, better access to necessary equipment and supplies, and less likelihood of transfer to or posting in rural sections of the country.

- **Recruitment by international organizations.** With increased international support for HIV treatment, international nongovernmental organizations (NGOs) and governments have become important employers of national staff. Increasingly, host country clinicians and program experts are being hired to run internationally funded program operations, effectively taking them out of the pool of health-care providers.

- **Donor reluctance to directly fund staffing.** Many countries have limited budgets to support continuous costs, including personnel, related to the design, implementation, and management of health-care systems. Donors, both bilateral and multilateral, have been reluctant to directly support human resource needs through salary and compensation benefits; this reluctance is largely due to concerns about sustainability. Only in rare cases, such as Malawi, has the donor community committed large-scale resources to address these challenges.4 Without adequate financial resources, it is unlikely that human resource needs, including ART initiatives, can be met for the public-health system.

- **Armed conflict and political instability.** A number of countries that embarked on ambitious ART roll-out campaigns have seen efforts slowed by internal armed conflict and political instability. Civil strife in Côte d’Ivoire, for example, has led to significant reductions in staffing at public and private service providers, as well as stock-outs of antiretrovirals (ARVs).5

- **Training needs.** HIV treatment, and in particular ART management, requires specific initial and continuing education through a combination of short courses and in-service training. Even the relatively minimal time required for training places a burden on health facilities, as they often have to arrange to cover those in training.

- **Vertical programs and competing demands.** HIV is not the only public-health priority in most countries implementing ART scale-up. Ministries of health and clinical facilities must address competing demands with insufficient human resources. The approach to program development and implementation has often been to establish vertical programs with limited or no overlap in service delivery or staffing. This often leads to inefficient or suboptimal utilization of critical staff, including physicians and nurses.

- **Shift from episodic or preventive medicine to chronic disease management.** Traditionally, public-health systems in resource-limited countries were developed to provide preventive (e.g., immunization) or episodic (e.g., prenatal, family planning) care services. The scale-up of HIV
treatment has required a shift to a chronic disease management model for both service delivery and staffing.

- **Provider stigma.** Provider stigma around caring for people living with HIV often complicates staff recruitment and retention. Directly related to this are provider concerns about occupational exposure to HIV, given the generally poor implementation of infection control programs and the limited access to postexposure prophylaxis (PEP).

- **Task assignment restrictions.** Professional associations and government regulatory authorities often have restrictive rules in place regarding the authority and responsibility for carrying out essential clinical care activities, including patient contact, counseling, and prescribing and dispensing pharmaceuticals. These restricted assignments limit a facility’s or program’s flexibility in adapting approaches according to local context and situations and often result in less-efficient and less-effective uses of already scarce resources. Barriers to implementing task shifting include system and organizational issues, such as the rules and regulations of national governments and professional organizations or facilities, as well as individual challenges, such as already overburdened staff and volunteers. Additional challenges include the need to develop and implement staff training and to revise supervision systems in order to monitor task assignment changes and to provide constructive, on-the-job assistance.

There has been increased recognition in the literature and at public conferences of the challenges regarding the human resource needs for ART scale-up. However, for program managers at the facility, district, regional, and national levels, there has been limited practical guidance in assessing human resource needs, developing approaches based on these assessments, and monitoring and making changes based on program evaluation.\(^2,3,6-11\) This chapter presents information and approaches for estimating human resource needs and identifies approaches and innovations to take into consideration as ART programs are developed, implemented, and monitored.

**METHODS FOR ESTIMATING HUMAN RESOURCE NEEDS**

The first step in determining the staffing needs for an ART program is to consider the basis for making these estimations. A number of approaches are commonly used for determining health-care human resource needs.

- **Population-based ratios.** Using the number of providers by cadre and the total population to be served, human resource need estimates can be made. As an example, a district hospital that provides a full complement of clinical services through a variety of programs could make estimates based on the number of specific cadres of staff who can provide services for the entire catchment area. So, in this instance, for every 5,000 people, there would be two nurses and one physician. The benefit of a population-based ratio is that it takes into consideration the broad community’s health needs and sets staffing levels according to the total number of health-care staff required. However, it does not take into consideration the complexity of different types of programs and whether proposed staff are appropriately trained and efficiently deployed.

- **Community health.** In this approach, ratios are determined using information about a community’s health and disease burden. Although more exact than general population-based ratios, this approach tends to look at health needs vertically, rather than examining opportunities for
collaboration and synergy across the system. For example, a health center may have identified five priority health issues—maternal and child health, child immunization, general surgery, HIV, and malaria—for which staff must be hired and trained. This health center would then fill the human resource needs for each vertical program, without examining opportunities for cross-training and for task assignment across program areas.

- **Target setting.** Increasingly, ART programs are being designed with explicit service delivery targets. In such settings and circumstances, these targets can be used as a basis for determining human resource needs. For example, if in one year, 1,000 people are to be newly started on treatment and 1,500 patients are to be maintained, what staffing levels are needed? This approach tends to focus vertically on specific HIV clinical care program initiatives and typically does not take into consideration the specific tasks necessary for achieving and maintaining quality services.

- **Task related.** In this approach, staffing levels are determined by examining the discrete tasks and steps necessary for completing a patient interaction. Each task required to ensure quality patient management is identified, irrespective of job title. Staffing needs are determined by the number and type of tasks, identifying appropriate people based on their skills rather than on their titles. This approach allows programs the flexibility of shifting assignments based on need rather than job title.

These approaches are not mutually exclusive. In many settings, the best approach may be one that merges a number of different approaches. For example, given the focus on targets in many programs, the ideal approach may be to examine targets alongside tasks and then make human resource estimates accordingly.

**FACTORS TO CONSIDER WHEN ESTIMATING HUMAN RESOURCE NEEDS FOR ART PROGRAMS**

Estimating staff needs for ART programs is a continuous process that must take into consideration numerous variables, many of which change over time. HIV prevalence and incidence, site experience, program stage (e.g., implementation, scale-up, and maintenance), and patient clinical status change over time and require reassessment of human resource needs and reallocation of staff. Therefore, program managers must continuously review staffing needs by revisiting different program parameters and making adjustments accordingly. The following are program factors that should be taken into consideration when determining staffing needs for ART programs.

**Service Model**

Clinical services offered to people living with HIV range from free-standing ART treatment centers to fully integrated efforts that combine HIV care with other primary health-care or infectious disease programs. Program placement decisions greatly influence and impact staffing levels. For example, although stand-alone ART treatment centers allow for higher patient-to-staff ratios, they also require a significant commitment of human resources to care for a relatively limited number of people, even in high-prevalence settings. The service model approach may also incorporate task shifting, which can maximize the use of specialized staff.

An increasingly common approach in high-prevalence settings is the integration of HIV treatment into primary health care. Yet this approach can result in providers specifically trained in HIV clinical management spending significant amounts of time tending non-HIV-related illnesses. From the health-system perspective, this is likely to be advantageous, as more patients can be seen in a more timely fashion and human resources can be
used to maximum efficiency. For people living with HIV, however, this situation may present challenges, as waiting times will likely be longer and actual time with the provider will be suboptimal from the patient’s perspective, though it may reduce separate referrals for non-HIV services. This integrated approach may reduce staff migration to well-financed HIV treatment programs. Like the HIV primary health clinic, this approach requires that significant attention be paid to task assignment.

**Existing Staffing Patterns, Responsibilities, and Available Resources**

Most ART programs are implemented within the context of ongoing HIV treatment efforts or primary health-care initiatives. For this reason, it is crucial to consider the current human resource needs for existing programs when determining additional changes in task requirements. To maximize staff efficiency and to utilize training and resources most effectively, staffing decisions should be made based on expected task assignments rather than on positions. For example, the number of people needed to conduct clinical follow-up assessments for patients on ARVs needs to be determined, with the understanding that the people conducting the actual assessment could be physicians, clinical officers, or nurses. Essential to this assessment is the determination of nonclinical needs, such as adherence counseling and referral for nonclinical services. In many settings, nurses undertake these functions; however, in some settings, these tasks are being shifted to lay counselors or appropriately trained and supervised peers. Continuing adherence support and outreach for missed clinical visits and pharmacy pickups are other critical tasks that should be reflected in task assignments and human resource determinations. Even if volunteers are used for these functions, appropriate staffing levels need to be calculated and supervision of volunteers must be taken into consideration.

**Schedule of Visits**

Expected frequency of clinical visits and pharmacy pickups will influence staffing needs. Directly related to these needs is the balance between enrolling new patients and maintaining patients already in care or on treatment. Increasingly, programs are implementing clinical visit schedules that differentiate between patients newly on ARVs and stable patients on treatment. For patients already on ARVs, the schedule typically evolves over time, with a more intense schedule of clinic visits in the first three to six months of treatment and then decreasing depending on stability. For patients not on ARVs, the typical follow-up schedule is two clinical visits per year. Regardless of the number and frequency of clinic visits, however, patients are typically expected to return to the pharmacy monthly for ARV pickup. The number and complexity of tasks to be completed during the pharmacy pickup (e.g., adherence measurement and support, dispensing) will help determine appropriate staffing levels. For both clinical visits and pharmacy pickups, protocols related to follow-up of missed visits will also influence human resource needs. If there is a system of active engagement for clients who have missed either type of visit, appropriate resources need to be allocated.

**Site and Program Factors**

No two sites or programs are exactly the same. Each has a unique set of circumstances and infrastructure that may support and enhance the ability to expand services or that may serve as a barrier to rapid, efficient, sustainable growth. Of particular importance in estimating human resource needs are (1) location (i.e., urban vs. rural), (2) physical space, (3) type of site (i.e., public, NGO, private, commercial, workplace), and (4) level of service and program integration. All factors are interrelated, and each directly impacts the ability of individual systems and programs to address short- and
ratios. Experience in many settings has shown that during the initial stages of implementing HIV treatment service delivery, enrollment in general and the number of patients placed on ART are low. These numbers increase as the staff gains greater confidence in patient management. In addition, as more patients are put on ART, there will be a shift from focusing primarily on initiating treatment to a situation in which starting treatment is part of a complex sequence of patient follow-up. This sequence may include long-term management of stable patients, more intense care for patients who have experienced treatment failure, and routine follow-up of all patients, with each task requiring a different mix of staff capabilities.

Staff training, attitudes, and characteristics

The success of any HIV treatment program depends in large part on the staff assigned to provide care to people living with HIV. A broad range of issues will directly impact human resource estimations. Some of these issues, such as training and prior experience, are tangible criteria that can be measured and assessed directly. Others, such as personal beliefs

long-term human resource needs. Box 1 presents issues raised by these factors.

Current Resources and HIV Clinical Service Experience

It has been well documented that most resource-constrained settings face significant staffing shortages in the health sector. In most countries, HIV treatment roll-out and expansion are only adding to this crisis. Where HIV care is being integrated into ongoing outpatient care services, the outstanding human resource needs must be taken into consideration. In many settings, this will require training larger numbers of providers to be multiservice providers. In instances where HIV clinical care is a stand-alone service, staffing to support active and efficient referral networks must be addressed. Regardless of the model of care, particular attention must be paid to nonclinical services and requirements, including drug dispensing, maintenance of medical record systems, and data collection and reporting requirements.

In addition to existing gaps in human resource needs, prior experience in providing HIV clinical care will impact staff needs and patient-provider ratios. Experience in many settings has shown that during the initial stages of implementing HIV treatment service delivery, enrollment in general and the number of patients placed on ART are low.
about behaviors related to HIV acquisition and people living with the disease, stigmatization, and fatigue, are often harder to identify and may serve as barriers to providing the highest-quality client-centered care. Provider characteristics, both tangible and intangible, will affect the time required by providers to care for individual patients and the ability of sites and programs to implement and scale services up and out. For example, if motivated staff are identified but have minimal or no training in general HIV care or ART management, significant resources and time will be required as the program is implemented. For more mature programs, issues of staff fatigue and burnout need to be considered, with appropriate shifts in tasks and patient load per provider being made as necessary.

Although many acknowledge that HIV prevalence in the health-care workforce is an issue, this prevalence is rarely directly addressed in human resource estimations. In general-population high-prevalence settings, some proportion of the staff is likely living with HIV. Providing clinical care for health-care staff living with HIV is important for supporting a stable workforce. In addition, anecdotal reports suggest that providing HIV care has lessened health-care worker stigma toward people living with HIV. Although HIV prevalence among the health-care workforce is an important issue, testing of any health-care workers should be voluntary, and confidentiality regarding individual HIV status must be protected at all times.

HIV Prevalence and Patient Profile

Prevalence of HIV in the community will greatly impact human resource needs, particularly for long-term staff planning. In the immediate future, as treatment programs are initiated either as integrated or stand-alone efforts, decisions about target populations will influence staffing needs. New HIV clinical services often focus on providing care to those in greatest clinical need. These patients tend to require more significant provider management, because they tend to have more clinically advanced HIV or have comorbid conditions, such as tuberculosis, that complicate care. Likewise, programs that identify pregnant women as a target population will likely have more complex human resource needs.

Although the initial patient burden often addresses those in greatest clinical need, it is expected that individual patient profiles, and therefore the overall population profile, will change over time. As access to and utilization of counseling and testing services increase and as there is more widespread implementation of opt-out testing programs, it should be anticipated that more people at an earlier stage of the disease will be identified. These largely asymptomatic patients will require less-intensive clinical management and will therefore require fewer human resources.

It is important to remember that none of these factors is static. Each factor will change repeatedly, evolving in response to factors directly and indirectly related to the HIV epidemic in a particular setting. The challenge for public-health professionals and health planners is to constantly review human resource needs, scanning the environment at the community and national level to identify shifts and to make appropriate changes. When possible, data should be used to guide changes in human resource need estimates.

Establishing Staff Plans and Strategies to Address Workforce Shortages

Establishing program- and site-specific staffing plans and strategies is not an exact science. It requires knowledgeable health-care workers and public-health planners who have an understanding of health-care service delivery in the country, as well as particular expertise and experience in the setting in which HIV clinical care services will be provided.
Of the approaches to human resource estimation presented earlier, two approaches are likely to best suit HIV treatment scale-up efforts. The preferable method is to take a team approach, which bases estimates on the need to complete specific and discrete patient care tasks. This approach allows for better utilization of often scarce resources, such as physicians, and gives sites and programs the flexibility to shift tasks in response to program and patient profile changes and staffing demands. However, as discussed earlier, this approach is not feasible in many situations due to regulatory or other reasons, and thus provider estimates are required. Although this approach often makes it simpler to calculate the estimates (e.g., for every 200 patients on ART, one physician is needed), it constrains the ability of sites and programs to respond quickly to shifting patient dynamics.

The following are issues to consider when estimating human resource needs for specific cadres of health-care workers, including program management. Together these issues represent the staff composition necessary to provide comprehensive, quality HIV care services.

Clinical Staff
Physicians, clinical and medical officers, and nurses form the front line of HIV care. Specific functions performed by members of each cadre vary widely according to site, program, and national guidelines. Across settings, these staff are collectively responsible for initial assessment and screening, determining ART eligibility, prescribing medications, providing follow-up care (including refills for existing prescriptions), authorizing regimen switches, referring for other clinical care, and, in many settings, providing general HIV counseling and adherence support. Some tasks may be allocated downstream in order to relieve the burden on the scarcest resources, typically physicians. This allows other adequately trained and supervised staff to manage routine care so that the greatest number of patients can be seen while providing maximum-quality care. For example, a clinical or medical officer is responsible for initial screening and eligibility determination, while nurses are responsible for follow-up of clinically stable patients with no comorbidities. This setup allows sites and programs to strategically use the expertise of trained physicians to address the needs of more complex cases, including regimen switches. It also requires shifting to other trained staff tasks typically performed by nurses, such as general and adherence counseling and tracking patients who have missed clinical visits.

Auxiliary Staff
Treatment and adherence support providers, as well as general counselors, are increasingly seen to be a critical part of a successful HIV treatment initiative. Many programs rely on trained, nonclinical staff to provide routine and ongoing support to patients regarding treatment adherence, nutritional support, prevention for positives, outreach for missed visits, and home-based care. The work required of this level of staff is intensive and often leads to provider fatigue and burnout. In estimating realistic human resource needs, nontraditional factors should be addressed, including distances that need to be traveled to follow up with clients who miss their clinical visits. The limited data available for estimating levels of staffing for this cadre of staff range between 10 and 20 patients per provider. Although shifting crucial nonclinical tasks to this group of providers may significantly relieve burdens at higher levels of the health system, supervision and ongoing education needs must be taken into consideration and assigned to appropriate staff.
BOTSWANA STARTED PROVIDING antiretroviral (ARV) medicines at public sector health facilities to the citizens in 2002. The ARV services started at four sites, where each site consisted of one hospital and four satellite clinics. Initially, the ARVs were prescribed by specialists and dispensed by pharmacists at the hospitals, while the clinics were limited to screening and pre-antiretroviral treatment investigations.

As more patients enrolled in the program, the challenges began to emerge, including patients traveling long distances to hospitals, congestion at the health facilities, and long queues and waiting hours, especially at the hospital pharmacies.

To mitigate some of the challenges, strategies to increase access to ARVs were developed. These included accelerating roll-out to the remaining hospitals and outsourcing the ARV services to private practitioners through the medical aid administrators’ public-private partnership. This resulted in temporary relief of the congestion, but following the approval of a routine HIV testing policy, more patients were identified as eligible, resulting in further long waiting times at all facilities.

Some of the patients started defaulting and cited travel logistics, such as lack of transport and financial constraints, as some of the reasons for not adhering to therapy.

The policy to roll out the ARV services to lower-level facilities (i.e., to allow the clinics to prescribe and dispense ARVs) was put in place. Major constraints included limited infrastructure for ARV storage, consultation and dispensing, as well as personnel shortages (especially pharmaceutical officers). Development partners offered to support the government by providing infrastructure and, where possible, providing personnel as project posts. However, recruitment of pharmaceutical officers lagged behind and remained a major bottleneck to the program. The policy to authorize nurses to prescribe and dispense ARVs was approved in 2006.

In Botswana, nurses are the pillars of the primary health-care system, as they form the bulk of the health-care delivery system. They are already involved in the prescribing, dispensing, and inventory management of medicines, even though they have not received formal training on pharmaceutical activities.

In 2007, the Botswana Harvard Partnership (BHP)-PEPFAR Master Trainer Program was mandated to equip nurses with the knowledge and skills to adequately manage and dispense ARV medicines to deserving patients. A four-day training program was developed to cover pharmacotherapy of ARVs, dispensing techniques, ARV medication adherence counseling, and appropriate ARV inventory.
management. This included quantification, the ordering process (procurement), receiving, and the appropriate documentation. The training consists of formal lectures, group discussions, role plays, and actual practical training at facilities. There is also a pre- and posttest.

After the training, the participants are mentored and monitored by the pharmaceutical officers at the hospitals or dispensing satellite clinics. A monitoring tool, consisting of the dispensing log for the participant and the performance log for the supervisor, is one of the tools used for evaluating the officer.

Training nurses in ARV drug management and dispensing has facilitated roll-out to the clinics. Services may be rendered on-site or as an outreach service. Eighty-five nurses have been successfully trained, and 25 clinics in the country are served by the trained nurses. In some facilities, the nurses dispense ARV drugs on their own, while in others, they dispense with pharmaceutical officers on a rotational basis.

The experience in Botswana has shown that with adequate training, nurses may play a pivotal role in ARV dispensing, especially where there is a shortage of pharmaceutical officers.

Technical Support Staff
Pharmacists and laboratory technicians are critical team members who are often underrepresented in HIV workforce estimations. In most resource-constrained settings, there is already a critical shortage of both laboratory technicians and pharmacists. Often, pharmacy and laboratory staff serve an entire facility and not a particular program. Therefore, existing workload burden and staffing gaps must be taken into consideration when adding HIV care. For pharmacists in many HIV clinical care programs, there is an expectation that they provide adherence counseling in addition to their dispensing and record-keeping responsibilities. In making determinations about pharmacist staffing needs, decisions need to be made regarding their role, if any, in adherence counseling, and estimates are needed for the time of patient-provider interaction. For example, a study in Zambia determined that for every 1,000 patients on treatment, 1.5 pharmacists were needed, with an average patient-provider interaction time of 8 minutes.10 Similar determinations need to be made at the site and program level. Likewise, for laboratory technicians, considerations regarding the scope of services and tests to be performed must also be considered when determining staffing needs.

Program Management
As clinical care programs become more complex and as program, administrative and financial management, and reporting requirements increase, there will be a growing need for qualified staff to fulfill these functions. In some settings, clinical staff assume some or all of these responsibilities. As human resource estimates are being made, discussions should include the appropriateness of this approach and should consider identification of staff responsible solely for program administration, including data collection, analysis, and reporting. As discussed previously, identifying the tasks that must be completed on a per-patient or monthly basis, while also taking into consideration patient volume, will likely result in the most appropriate staffing levels.

No one-size-fits-all calculation allows a facility or program to enter the current or projected
number of people enrolled in HIV care and to receive in return a staffing figure and pattern. Human resource needs must be adjusted to address the current situation, building on assets and taking into consideration existing constraints. It is also critical to remember that staffing needs are not static. Staffing levels need to be routinely reevaluated, using patient load and staff efficiency data to make adjustments in task assignments. Existing staff should be trained to take on new or different responsibilities, and appropriate staff should be hired to address critical gaps, if necessary.

CONCLUSION
The past five years have seen tremendous success in expanding access to and utilization of HIV clinical care. National and international resources have been mobilized to meet demand, and today people living with HIV are living longer because of these efforts. However, during this time of rapid expansion of service delivery, we have learned that a critical need is additional human resources to meet current and projected staffing needs. Sites, programs, and national governments are demonstrating flexibility in task assignment and in the use of nontraditional staff. In the coming years, continued attention must be paid to human resource needs to ensure that eligible patients are enrolled in HIV clinical care and that those already enrolled continue to receive the highest-quality care possible. This will require a commitment at all levels of local, national, and international health systems to continuously monitor human resource needs and provide the necessary resources.
REFERENCE LIST

A comprehensive response to human-resources-for-health (HRH) challenges requires both macro- and micro-level interventions. Macro-level interventions are well suited for international- and national-level action. At the service delivery level, however, institutional and micro-level interventions are required to attract, train, and retain health workers in sufficient numbers. These workers must then be equitably deployed and consistently motivated to provide high-quality services. The second High-Level Forum on Health Millennium Development Goals (MDGs), held in Abuja, Nigeria, in December 2004, acknowledged that unless action is urgently taken to address the HRH crisis, many countries will fail to reach the MDGs. It was acknowledged at that time that this failure would represent not merely a missed deadline but a real calamity for the impoverished citizens of the affected countries.¹

The HRH crisis is being experienced by fragile health-care systems in many developing countries and is the result of several macroeconomic factors as well as poor governance. This crisis, while longstanding, is compounded by the magnitude of the HIV pandemic, which has led to excessive workloads and burnout, high worker attrition rates, and limited entry of young professionals into the workforce. Any solutions to this crisis must therefore address broader macroeconomic factors as well as the local conditions influencing the availability of human resources on the ground. The World Health Organization (WHO) 2006 World Health Report included global, regional, and country-level profiles of workers in the health sector and provided new data on health worker demographics. It also provided recommendations for the future development of HRH from the WHO-led task-shifting consortium.³

According to the Global Health Workforce Alliance, in 2006, sub-Saharan Africa, home to about 11% of the world’s population, bore more than 24% of the global disease burden; yet it was home to just 3% of the global health workforce and spent less than 1% of the world’s financial resources on health. In most developing countries, the health workforce is concentrated in major towns and cities, while rural areas, on average, contain only 23% of the country’s doctors and 38% of its nurses.⁴ Imbalances exist not only in the total numbers and geographical distribution of health workers, but also in the skills mix of available health workers. WHO estimates that 57 countries worldwide (36 of
which are in sub-Saharan Africa) have such a critical shortage of health workers that the countries would need to increase their health workforce by about 140% to achieve enough coverage for essential health interventions in order to make a positive difference in the health and life expectancy of their populations.⁵

**REASONS FOR THE HUMAN RESOURCES CRISIS**

The major challenges to building an effective health-care workforce in developing countries include

- low absolute numbers of trained health workers;
- difficulties in recruiting, retaining, and managing health workers;
- the impact of HIV on the health workforce; and
- poor health-worker performance.

**Low Absolute Numbers of Trained Health Workers**

In many developing countries, the capacity for training health workers is limited. For example, Ethiopia, with a population of 75 million, trains about 200 doctors a year, whereas the United Kingdom, with a population of 60 million, trains more than 6,000 doctors a year.⁶ Two-thirds of the countries in sub-Saharan Africa have only one medical school, and some countries have none.⁷ In addition to the low capacity for training, there is a growing sense that in sub-Saharan Africa, the medical profession—and the clinical disciplines in particular—have become less attractive to new entrants due to low salaries in the public sector, low morale among existing health-service providers, dilapidated health systems, and fear of HIV infection. These factors need to be researched further to understand the role they play in attracting and retaining a high-quality health-care workforce.

**Difficulties with Recruitment and Retention**

Many facilities face difficulties in recruiting and retaining health staff. An important reason for this challenge is that health workers often migrate to find better opportunities. This migration includes international migration, internal rural-to-urban migration, migration from clinical to administrative jobs, migration from the public to the private or nongovernmental organization (NGO) sectors, or migration out of the health-care sector entirely.

Both push and pull factors are associated with migration. Push factors are those negative factors that lead to dissatisfaction with where the health worker currently works. Low wages, lack of additional training opportunities, poor working and living conditions, and lack of social and retirement benefits are commonly cited push factors.⁸ Pull factors are those factors that make other potential jobs or areas more attractive, including higher salaries, better working conditions, better benefit packages, training opportunities, and recognition of good performance.⁹

In a 2004 analysis of staff loss rates in Zambia, Huddart et al.¹⁰ showed an annual rate of loss of 20% for clinical officers and 36% for midwives, with loss rates for doctors and nurses falling somewhere in between. In Malawi, death and resignation were the main causes of health-care worker attrition (Figure 1).¹¹ Deaths often result in posts being left vacant because no additional staff are available to replace those who have passed away.

**Impact of HIV Infection on the Health Workforce**

In the study by Gonani et al.¹¹ death contributed 48% of health-worker attrition—with 73% of these deaths attributed to HIV—making HIV a significant threat to HRH. The Joint Learning Initiative has identified three ways in which HIV poses a great threat to the health workforce.¹² First, HIV
is associated with increased workloads and skill demands; second, health workers frequently fall ill and die from HIV infection; and third, health workers must cope with the psychosocial stress of caring for increasing numbers of dying patients, in addition to caring for their own sick family members. In addition, fear, stigma, and discrimination affect worker motivation and performance.

A major concern among clinical service providers and other support staff in developing countries is the risk of contracting an infection such as HIV in the course of performing their regular duties. In studies conducted in Kenya and Malawi, 9 out of 10 health managers perceived the risk of HIV infection to be high or very high. Reasons for this perception included lack of skills in infection prevention, delays in investigation of patients (e.g., those with signs or symptoms of TB), and lack of protective materials due to stock-outs and staff negligence. These fears led providers to avoid performing certain tasks or to leave clinical service altogether.

A study in South Africa found that 11.5% of health workers in two public hospitals were HIV positive. The proportions were highest among nurses, student nurses, and younger staff. Of those living with HIV, 19% had CD4 counts below 200 cells/mm³ and were therefore eligible to receive antiretroviral therapy (ART). In addition to directly affecting the lives of health workers, the HIV epidemic has led to widespread fear of infection, increased workload, and burnout. Research in Swaziland has suggested that these factors can lead to significant decreases in the quality of health-care services.
There is also fear that the rapid scale-up of ART, because it is so labor intensive, will negatively affect other non-HIV-related health programs. However, early evidence suggests that the number of health worker lives saved by ART may offset the additional human resources needed to implement HIV treatment programs.17

**Poor Health Worker Performance**
In addition to problems created by the lack of absolute numbers and the inequitable distribution of health workers, there is also the problem that health workers do not always provide an acceptable level of care. In a 2005 review of this issue published in *The Lancet*,18 it was found that determinants of health workers’ performance included their knowledge, skills, motivation, and experience, and attitudes toward their job, workplace, and patients. The review also listed nonhealth-worker factors, such as the quality of the guidelines workers are expected to follow and the health facility environment (e.g., workload, availability of equipment, attitudes of co-workers and supervisors, and the degree of control workers have over the work environment), as well as external factors, such as the socioeconomic and political environments of the country or region in which the workers are practicing.

A study by Manongi et al.19 explored the experiences of health workers in the primary health-care facilities of the Kilimanjaro region of Tanzania. The study looked at workers’ motivation, satisfaction, and frustration and attempted to identify areas in which sustainable improvements to services could be achieved. It was discovered that the primary factors influencing worker motivation were the complexities of multitasking in the context of staff shortages, a desire for more structured and supportive supervision from managers, and improved transparency in career development opportunities.

**STRATEGIES TO ADDRESS HRH CHALLENGES**

**Increase the Number of Trained Health Workers**
Efforts to train existing health workers in developing countries are growing as wealthier nations increase aid to these countries and recognize the futility of providing lifesaving medicines in the absence of properly educated medical personnel. National governments of developing countries are also beginning to increase investments in training more health workers, but these investments have so far fallen short of what is needed.

Some innovative approaches to increasing the number of trained health workers and for developing training programs to address some of the maldistribution problems have been attempted in various countries. For example, some countries offer free medical training to students from developing countries. Cuba graduated nearly 4,000 international students from its medical schools between 1966 and 2004.20 Medical schools within developing countries have also been founded or expanded using funds from international donors, including governments, nongovernmental development agencies, or medical schools in wealthier countries.21 Increasing the number of medical trainees will not necessarily solve all aspects of the workforce crisis. Egypt, for example, trains more physicians than it needs, but because of the low remuneration for working in rural areas, doctors often prefer to leave the country or leave the profession rather than move to rural areas.22

**Recruitment and Retention**

*Decrease the Barriers to Hiring New Staff*
The Capacity Project, an initiative supported by the United States Agency for International Development (USAID), has worked with health sector leaders to develop the Emergency Hiring
Plan (EHP), a rapid-response staffing and training model designed to increase the number of qualified health professionals available to work in public health facilities. The EHP is helping the Kenyan Ministry of Health expand access to treatment and care through rapid hiring, training, and deployment of 830 health workers. This aid has shortened the recruitment process from more than a year to three and a half months. The new hires are given three-year contracts; afterward, the Ministry of Health absorbs them into the regular workforce. EHP hires also receive a two-week training session prior to starting work to update their HIV-related clinical skills. Once these workers are absorbed into the permanent service of the Ministry of Health, they receive routine in-service training alongside other regular staff.

Reduce Internal Migration

Whereas most workers identify salary level as an important push or pull factor, it is not the only factor in worker retention. Good accommodations, the quality of health-care facilities, and the welfare of the worker’s entire family are all important in the professional development of health workers. Attention to these factors has been shown to improve retention in high-income countries. A common strategy for increasing the number of health workers in rural areas is to provide training for students who come from rural areas. A wealth of evidence from developed countries indicates that students from rural areas are more likely to practice their profession in rural areas. This finding also holds true in South Africa and Thailand, where medical students from rural areas are more likely to return to those areas after graduation. Even if students do not originate

Decrease Rural/Urban Health-Care Inequities

The unequal distribution of health staff is a significant challenge for rural facilities. For example, in Nairobi, Kenya, there is one doctor per 500 people, whereas the remote Turkana district of Kenya has one doctor per 160,000 people. Countries have used a variety of strategies to reduce geographical disparities, including increasing training opportunities for students from rural areas, providing a rural experience during pre- or postgraduate training, increasing the number of nonspecialist trained staff, and providing financial and nonfinancial incentives for health workers in rural areas. A common strategy for increasing the number of health workers in rural areas is to provide training for students who come from rural areas. A wealth of evidence from developed countries indicates that students from rural areas are more likely to practice their profession in rural areas. This finding also holds true in South Africa and Thailand, where medical students from rural areas are more likely to return to those areas after graduation. Even if students do not originate
from rural areas, providing rural experiences during pre- or postgraduate training can increase the chances of their practicing in rural areas. Again, although much of these data are from developed countries, evidence also exists from Ghana and Thailand that providing rural training experiences will increase the chance of trainees accepting a rural position. Another strategy is to increase the number of general physicians trained. Brazil and Canada have attempted this strategy based on the assumption that generalists are more likely to move to rural areas.

In addition to making changes in the education of medical professionals, governments have provided incentives to recruit and retain staff in rural areas. South Africa, for instance, has introduced an 8% to 22% salary bonus for staff working in rural areas, depending on the cadre of staff and the rural designation of the placement. A survey conducted soon after this program was implemented found that 28% to 35% of staff in rural areas had decided to stay for the next year because of the rural allowance. According to another South African study, rural doctors stated that higher salaries would have the most effect on retention in rural areas but that nonfinancial incentives were also important. The three most important nonfinancial factors identified in this study were suitable accommodation, a good hospital environment and working conditions, and increased career opportunities. At least one of the doctors interviewed also listed access to continuing medical education, recognition and appreciation, and good staff relationships as important factors in retention.

Decrease Staff Turnover
Most of the data on reducing staff turnover come from fields outside of health care or from health-care systems in high-income countries. In the following sections, we will review the general principles from these fields and then discuss examples of how these principles have been practiced in developing countries.

Husselid examined the association between human resource (HR) management practices of 968 American companies in various fields and their turnover rates, productivity, and financial performance. He grouped HR management considerations into two categories: (1) employee skills and organizational structures and (2) employee motivation (see Box 1).

The average annual turnover across all the companies in Husselid’s study was 18%. Companies that received higher ratings for employee skills and organizational structures had lower turnover rates. The factors relating to employee motivation were not associated with turnover. The author felt that although paying attention to motivation would help decrease turnover, performance appraisal and linking compensation to performance could increase turnover by causing weak staff members to leave. The same study found that staff productivity and company financial performance are both positively associated with good employee skills, good organizational structures, and employee motivation.

Within the health-care field in developed countries, a number of studies have examined the characteristics of hospitals with low turnover rates and the reasons staff members choose to leave a given facility. The NEXT Study Group compared the opinions of 1,175 nurses from hospitals with low and high turnover rates. Nurses from the low-turnover hospitals perceived fewer job opportunities in their local area, but they also expressed more positive feelings about the hospital where they worked. For instance, those nurses had a shorter commute, recognized lower exposure to hazards in the workplace, had more control over their work schedule, were happier with their roles and the latitude to make decisions in their jobs, and had a better effort-reward ratio. They also recognized better relationships with management.
Africa (Angola, Botswana, Republic of Congo, Kenya, Lesotho, Madagascar, Malawi, Mauritius, Mozambique, Namibia, South Africa, Swaziland, Tanzania, Uganda, Zambia, and Zimbabwe), health workers receive a variety of nonfinancial incentives, including training and career path incentives, housing, transportation, child care, improvements to facilities, and security. Of the 16 countries assessed, 15 had also developed HR information systems.

Reduce the Effects of HIV
The first step in reducing the direct effects of HIV, as well as the stress related to the fear of infection, should be the introduction of good infection control procedures to protect health workers from nosocomial HIV infections. The use of postexposure prophylaxis to be taken in the event of a needle

management and support approaches that lead to higher levels of performance and improved outcomes. For example, in a study to gather examples of how different service delivery organizations in Guatemala try to manage and improve the performance of their staff, it was found that availability of resources is a key factor in influencing staff performance. Providing resources to carry out fieldwork and offering salaries that are competitive within the national labor market appeared to have the greatest influence on staff performance. Additional important influences for ensuring improved performance included supervision linked to support for the performance of clearly defined individual tasks, coaching and mentoring, measuring, and monitoring.

Quality Improvement Methods
Over the years, the Quality Assurance Project (QAP)—the predecessor of the Health Care Improvement Project implemented by University Research Co. LLC—has been involved in using quality improvement methods to help provider teams identify barriers to providing effective and efficient health care and to develop solutions to these problems. This approach has led to more motivated staff, improved service delivery systems, and improved care outcomes. Examples of programs that have utilized this approach with subsequent improvements in staff performance and outcomes are presented on the QAP Web site (http://www.qaproject.org). Some of the improvements achieved by these programs include decreased postpartum hemorrhage, improved compliance with standards of care, improved adherence to antiretroviral (ARV) medicines, better triaging of children with serious illnesses, and better outcomes of emergency care, such as reduced deaths within 24 hours of admission. Importantly, these improvements have been made by changing the process of care delivery and without increasing the number of health-care workers.
THE PERFORMANCE OF A HEALTH care system is only as good as the performance of the service managers and care providers within that system. Illustrating this point are findings of a 2003 study from Vietnam investigating factors influencing job motivation among rural health workers. According to the authors of the study report, managers and policymakers considered supervision to be an important tool in controlling the work of health workers; this supervision took place regularly, though the frequency varied for each level of staff. The authors considered supervision to be integrated to some extent, as all activities were checked during a single visit. However, according to them, the vertical programs had their own supervision system. For example, health workers perceived supervision as a means of controlling their work plan without providing feedback, and positive feedback was lacking when the health workers performed well. This point is illustrated by the following comment from a staff member of a preventive health team at the district level:

During supervision of the provincial program, such as for malaria, the supervisor comes and looks at the record books. If there is something wrong we sit together and fix it. But there is no feedback, and sometimes I don’t know if my work is acceptable or not.

Feedback is one way for managers and colleagues to show appreciation, which was found to be the most important motivating factor for health workers in the Vietnam study.

In this study, staff appraisal, including evaluation of the health facility, took place biannually, as explained by the managers interviewed. As part of this appraisal, health workers had to assess themselves in writing and assess the team during a meeting. The health workers considered the appraisal to not be very useful and saw it mainly as an administrative exercise. They had the feeling that they could write anything they wanted. As one community health center staff member remarked,

We send the appraisal report to the district health center in a certain period and in the report we write down what we have done and we give a self assessment, but we always assess ourselves positively. The result will affect the assessment of the group.

Appreciation can be shown during performance appraisal and can serve as an important entry point for staff motivation. According to managers and policymakers, an additional token of appreciation commonly used in Vietnam is the award system, which is linked to the biannual appraisal. Awards, in the form of money, certificates, or other tokens, are given to people who are assessed as excellent workers. Although its value has decreased over the years, the award system is still appreciated by health workers. Apart from the award system, however, other strategies to motivate staff are not commonly employed.
CHANGES IN HEALTH CARE SERVICE DELIVERY

Highly skilled doctors are not available in large enough numbers to provide services to the majority of clients, especially in rural areas. One solution to address this is task shifting to well-trained lower-level cadres of service providers—for example, clinical officers and nurses instead of doctors. Different countries have a variety of locally trained indigenous health professionals—clinical officers in Malawi and Zambia, surgical and medical technicians in Mozambique, assistant medical officers with surgical and obstetric skills in Tanzania, and medical assistants in Ghana. The medical licentiates and clinical officers in Tanzania are trained to diagnose, treat, and prescribe and can therefore fulfill many functions in district hospitals that the shortage of doctors would otherwise have made impossible. Likewise, nurse practitioners in Swaziland and enrolled nurses in Malawi have played immense roles in their health systems, particularly in remote areas where it is difficult to get better-qualified health professionals to practice. These cadres typically require two to three years of postsecondary training, rather than the five to six years required for medical doctors.

Data show that tasks previously performed by doctors can be performed equally well by both nonphysician clinicians and nurses. Other data support the use of lay health workers to effectively deliver malaria treatment, increase immunization uptake, and improve treatment of TB. Mounting evidence also indicates that nonphysician practitioners (primarily clinical officers and nurses) can, with adequate training, deliver ART to HIV-positive patients.

A few studies have documented the effectiveness of using nonphysician providers and lay health workers to increase capacity for HIV-related services. In 2003, a study conducted at 16 health-care sites in Zambia offering various HIV-related services (e.g., voluntary counseling and testing, prevention of mother-to-child transmission, and ART) demonstrated that it is possible to improve performance through the use of trained laypersons.

In Mozambique, an intervention involving nurses performing CD4 lymphocyte counts, when implemented correctly, was associated with a more rational use of higher-level clinical providers, which may improve overall clinic flow and efficient use of the limited HR supply. However, this particular intervention did not lead to an increase in the number of patients starting ART or a reduction in the time to ART initiation. The length of time that the program had been operating played an important role in all outcomes, suggesting that general improvements in clinic efficiency may have overshadowed the effect of the intervention. The lack of observed effect in these outcomes may also be due to additional health system bottlenecks that delay the initiation of treatment in ART-eligible patients.

More studies are needed to clarify the impact of changes to service delivery on the health workforce, particularly in light of increased global support for task shifting as a means to support the rapid scale-up of services. Although no one solution is available or feasible, the overall goal should be to get the right health workers with the right skills in the right place and doing the right things. Although each country is unique, each can and should learn from the experiences of others—best practices abound and need to be shared.
NE OF THE KEY CONSTRAINTS to the expansion of HIV services in resource-limited settings is a serious shortage of human resources for health. The shortage of well-trained health workers is global, but resource-constrained countries, particularly those in Africa, feel the crisis most acutely (see Figure 1). Put simply: there are not enough health workers to deliver on the target of universal access to HIV services.

The health workforce crisis is multifaceted and demands a comprehensive response that is aligned with broader health systems strengthening, including strategies to protect the health of the workforce and to treat those who are sick, to retain health workers in their jobs, and to train new and greater numbers of qualified professionals.1,2 There is also a need to seek innovative ways to make the best use of the available human resources for health and to quickly expand capacity. Many countries have responded pragmatically by adopting a task-shifting approach. This involves redistributing tasks rationally among health workforce teams so that specific tasks are moved, where appropriate, from highly qualified health workers to health workers with shorter training and fewer qualifications. Where further additional human resources are needed, task shifting may also involve the delegation of some clearly delineated tasks to newly created cadres of health workers who receive specific, competency-based training (see Figure 2). For example, in Malawi and Uganda, the basic care package for people living with HIV has

been designed to be delivered by nonspecialist doctors or nurses, supported by community health workers and people living with HIV. Similarly, Ethiopia has implemented a plan to train and hire community health workers to expand the current workforce delivering HIV services. This can free up the bottlenecks in service delivery and support a rapid expansion in the availability of HIV services, especially at the community level.\textsuperscript{3}

In January 2008, the World Health Organization (WHO) published a series of evidence-based recommendations and guidelines that represented the culmination of a broad-based process of consultation and evidence-gathering lasting more than two years.\textsuperscript{4} The WHO Global Recommendations and Guidelines on Task Shifting provide an authoritative framework that can help support and guide widespread implementation in countries that choose to adopt the approach as a national strategy for organizing the health workforce. This framework aims to bring clarity to the task-shifting experience and to identify and define the conditions and systems that must be in place if the approach is to prove safe, efficient, effective, equitable, and sustainable.

Note: PLHIV = people living with HIV

Figure 2. Task shifting: expanding the pool of human resources for health

The recommendations and guidelines cover the need for consultation, situation analysis and national endorsement, and the need for an enabling regulatory framework. They specify the quality assurance mechanisms, including standardized training, supportive supervision, and certification and assessment, that will be important to ensure quality of care. The guidelines also cover the elements that will need to be considered for the purpose of ensuring adequate resources for implementation and offer advice on the organization of clinical care services under a task-shifting approach.

At the International Conference on Task Shifting in Addis Ababa, Ethiopia, the WHO Recommendations and Guidelines were endorsed in the Addis Ababa Declaration, which was unanimously adopted on January 10, 2008.6

Recent interest in task shifting has been accelerated by the need to urgently respond to the HIV pandemic with a rapid expansion of treatment and care. Task shifting, however, involves rationalizing and decentralizing the way in which all health services are delivered and embodies the core principles of public health services that are accessible, equitable and of good quality. As such, task shifting also offers long-term potential for all primary health-care services and for overall health systems strengthening.

Note: The WHO Global Recommendations and Guidelines on Task Shifting can be downloaded at http://www.who.int/healthsystems/task_shifting/en/.

CONCLUSION

A major challenge to delivering quality services in developing countries is the growing shortage of trained health workers in countries already burdened with insufficient infrastructure, poor government health-care systems, and extreme poverty. Academic institutions lack the resources and faculty to produce enough qualified physicians. Doctors and nurses are leaving their home countries for better-paying jobs in developed countries or are migrating toward urban areas. Health-care professionals are also dying from the very infectious diseases they are needed to help prevent and treat. Overdependence on highly trained professionals, such as doctors, will thus limit the ability of these countries to scale up access to services.

Ultimately, in order to cope with these human resources challenges, it is essential to address both institutional and individual factors. Approaches at the institutional level include improved workforce management systems that pursue equitable distribution of health workers, staff inclusion in staffing-related decision making, clear job descriptions, improved communication between management and staff, supportive supervision, mentoring, and coaching. Approaches at the individual level include monetary and nonmonetary incentives, performance appraisal, career development, and task shifting linked to increased skills development. An effective response therefore requires a comprehensive approach that addresses institutional, facility, and individual factors in a holistic manner, while taking into consideration the needs and dynamics of the entire health-care system.

Caring for Caregivers: Lessons Learned in Addressing the Needs of Health-Care Workers Affected by HIV/AIDS

Michael Vitols, a Dorothy Gillian Ngoma, b Olive Ngandu, c and Isaac Sulwe c

aNorwegian Nurses Organization, Norway
bNational Organization of Nurses and Midwives of Malawi, Malawi
cZambia Union of Nurses Organization, Zambia

The NORWEGIAN NURSES Organization (NNO) is working in partnership with the Zambia Union of Nurses Organization (ZUNO) and the National Organization of Nurses and Midwives of Malawi (NONM) to assist nurses who are infected or affected by HIV/AIDS. This article shares experiences and insights gained, primarily in Zambia but also in Malawi, from the implementation of the “Caring for Caregivers” projects in both countries.

The Caring for Caregivers project has been operating in Zambia since 2003, and a similar project was initiated in Malawi in 2006, drawing on the experience gained in Zambia. We believe that what we have learned can be of value to nurses and nurses associations in similar resource-limited settings. If nurses and their nurses associations in countries such as Zambia and Malawi can be mobilized, encouraged, and empowered, then this should also be possible in other countries facing similar circumstances.

Nurses in resource-limited settings regularly face a number of challenges, including high patient loads, lack of psychosocial support, limited infrastructure, and limited opportunities for professional development and/or continuing education. Such burdens can easily lead to apathy and professional “paralysis.” Nurses in these situations may often find themselves simply attempting to get through one day at a time, hoping and praying that they, along with their patients, will survive.

PROJECT DESCRIPTION
The development of the Caring for Caregivers project was based on the results of a needs assessment survey that used both qualitative and quantitative research methods. Nurses in Zambia and Malawi were asked to articulate their needs and concerns, with the results of the survey providing an empirical basis for the project design.

The main objective of the project was to provide care and support to nurses and other healthcare workers. In Zambia, care and support activities were limited to nurses. Based on the project’s experiences in Zambia, the target population in Malawi was expanded to include other health-care workers. Desired outcomes included the provision of updated knowledge on HIV/AIDS, development and implementation of routines for infection prevention and control, and the creation of local
support groups to provide psychosocial and financial support to HIV-infected and affected health-care workers.

At first, the concept of caring for caregivers was not so easily understood or accepted, even among health-care professionals. Many asked, “Why should nurses be given preferential treatment?” or, “Can they not queue up for treatment together with their patients?” As nurses, we serve not only as professional caregivers but also as positive role models. For many nurses, the idea of publicly displaying a need for treatment is simply too embarrassing or shameful. This is especially true if the nurse suspects that he or she is HIV infected, due to the social stigma attached to this diagnosis. As a result, many choose not to seek treatment, preferring illness and a potentially early, unnecessary death over the consequences of disclosure. Other times, nurses may seek treatment far away from home so that they can remain anonymous, only to have their treatment interrupted or fail due to their inability to travel on a regular basis.

The Caring for Caregivers project was a creative response to these challenges. The mission of the project was simple and clear: nurses were getting sick and dying, and they were in need of special attention. The illness or loss of these nurses was being felt by the greater community as well, since shortages of health-care workers result in limited or diminished care. Indeed, without enough healthy nurses, how can a community remain healthy so that fields can be tended and businesses can be run? A prerequisite for a healthy community, a healthy workforce, and a healthy nation is the availability of enough health-care workers to provide quality care.

The Caring for Caregivers project consisted of four major interventions:

1. Nurses were provided with updated knowledge about HIV/AIDS. Many nurses had no formal HIV/AIDS training and had seldom if ever attended workshops or refresher courses (this was especially true among those living in rural areas).

2. A countrywide list of voluntary counseling and testing (VCT) centers was compiled and presented to workshop participants. Nurses were encouraged to be tested and were offered the option of being tested in a neighboring town if they felt that confidentiality might be compromised in their home areas.

3. In Zambia, procedures for infection prevention and control in the workplace were developed, tested, and implemented. These procedures were approved and adopted by the Zambian Ministry of Health for all health-care institutions.

4. Local support groups were established so that nurses could start income-generating activities to provide money that they could use to help each other. These support groups also served as gathering points for nurses to provide psychosocial support to each other, breaking the bonds of secrecy, silence, and stigma.

CREATING LOCAL SUPPORT GROUPS

Formation
Local nurses had to take a series of steps in order to establish a local support group. First, support group leaders had to gather 30 interested nurses. The nurses then organized themselves, electing a chairperson, secretary, and treasurer, and opened a local bank account. Leaders collected fees from the members for the support group and deposited them in the newly opened bank account. They also developed a written proposal for the support of income-generating activities that was then sent to the project coordinator and project manager for review, alteration if needed, and approval. Only
then was the group qualified to receive seed money, usually US$1,000 or US$500.

The success of these support groups was dependent on close collaboration, from the very beginning, with the administration and management of the local heath-care institutions. Their support and understanding was invaluable.

**Support Activities**

While the support groups at the beginning were quite focused on starting their income-generating activities, they were continually encouraged by the project managers (respected nurses) to reach out and help each other by providing psychosocial support. Nurses often know when a fellow nurse is ill. Instead of silently noting their colleague’s illness and absence from work and doing nothing about it, they were encouraged to actively help him or her. The saying ”No nurse should get sick and die” became a standard phrase used by project staff when speaking with nurses in the various local support groups around the country.

At the beginning, nurses often paid for food and medicine for sick colleagues from their own pockets. As the support groups began to make money, they were able to more actively support sick nurses. Support could come in the form of food and medicine purchases, paying for someone to clean the sick nurse’s home, or financial support when the nurse, as a family breadwinner, was incapacitated over a lengthy period.

Support groups also sought out the orphaned children of deceased nurses and paid their school fees as well as providing for other basic needs. This created a strong impetus for nurses to become members of their local support groups, as they realized that their children would be looked after by their colleagues in the event of their own illness or death. Money was also provided so that deceased nurses could be given proper burials.

Eventually, support group activities began to focus more on psychosocial and emotional support than on financial support. However, the ability of nurses to provide financial support to those in need added to their empowerment.

**Income-Generating Activities**

The specific types of income-generating activities undertaken were left to the imagination and decision of the local nurses. Circumstances differed from area to area, and the local nurses often knew best what types of activities might be able to generate a profit. The following are examples of activities that were successfully executed:

- “Tuck” shops (kiosks or small shops) selling low-cost items such as soft drinks, snacks, and telephone cards
- Poultry farming
- Pig farming
- Catering
- Tailoring
- Cafeteria
- Pool table rental
- Health-care checks (blood pressure and weight) for a fee

**GROWING PAINS**

The establishment of income-generating activities requires some level of business skills. Accounting, marketing, and separating capital expenses from operating costs are concepts that most nurses in the support groups were not familiar with. On discovering that greater supervision was needed, at least initially, to help familiarize the nurses with the running of a small business, the project leaders decided to increase the level of monitoring and counseling being directly provided to each local support group by project staff. This was a major undertaking, considering that the project had created over 80 support groups in Zambia, spread out across the country. It was also decided that a
three-day small-business-skills workshop would be
offered to support group representatives.

In several of the support groups, problems were
noted due to some nurses not sharing informa-
tion, not agreeing on how funds should be used,
not working well together, or not depositing
funds in the support group bank account. Most of
these “growing pains” were due to personal issues
and required some mediation from project staff
to resolve.

As expected, another challenge involved getting
nurses to commit their time and personal effort to
establishing and building the support group, since
most nurses were already terribly overburdened
and had little if any free time. Fortunately, having
at least 30 nurses in each support group usually
provided enough human resources and a dedi-
cated core of nurses who were able and willing to
put in the extra effort required. It should be noted
that the establishment of local support groups had
a strong psychological effect. We called it “the psy-
chology of hope,” the idea being that if we could
give nurses renewed hope by showing them that
they had not been forgotten, but rather were being
cared for and cherished, then they would respond
by mobilizing and playing their part. This proved
true in Zambia, time and time again, and is also
proving to be true in Malawi.

UNEXPECTED GAINS
As part of project implementation, a separate
research project was carried out by an external
researcher to evaluate the effectiveness of local
support groups. Responses from questionnaires
and focus group discussions revealed that a major
unexpected gain was the sense of unity and purpose
that had developed among the nurses. Previously,
there had been little or no contact between junior
and senior nurses, between privately employed and
public nurses, or between staff and administra-
tion. The newly established support groups often
represented a cross section of these groupings, and
by coming together during workshops and through
their local support group activities they were able
to forge a new sense of unity and purpose.

THE ROLE OF THE NATIONAL
NURSES ASSOCIATION
Local support groups will not function efficiently
over time without the support of a strong national
nurses association. Support groups require some
form of regular contact and monitoring. If this
contact is not provided, many will gradually
lose momentum and become dysfunctional. The
national nurses association benefits from its sup-
port of these groups by having a well-developed
network of nurses at the grassroots level.

FOR NURSES ONLY OR FOR ALL
HEALTH-CARE WORKERS?
One of the lessons learned during the Zambian
project was that local support groups in rural areas
often ran into a bit of trouble when other health-
care workers felt excluded from participation.
Nurses have been, and generally still are, an under-
privileged group within the health-care sector, and
many feel quite strongly that the support group
they have worked for and created is “by them and
for them.”

In Zambia, we chose to let the support groups
remain support groups for nurses, and not for-
mally expand them to include other health-care
workers. However, each support group can decide
who it wants to support, and if there are good rea-
sons for supporting a non-nursing colleague, then
the group is free to do so.

In Malawi, the main project also includes other
health-care workers. However, the activity is still
being initiated and run by nurses and should,
therefore, remain under the control of the nurses.

It should be noted that a gender issue is
involved here. Nurses are mostly female, while
other health-care workers (medical doctors, clinical officers, etc.) are mostly male. The nurses expressed concern that their male colleagues were interested in joining their support groups, reaping the benefits of the income-generating activities, and even taking control of activities, and that this might be at the expense of some of the needs of the female nurses and their families. Also, some nurses expressed indignation, saying that we, as nurses, were neglected for such a long time, and now, when we finally have something being done “by nurses, for nurses,” suddenly other health-care workers also want to share in the benefits. These are issues that need to be addressed and discussed in an open and honest manner.

We are still in the early days in Malawi in terms of the establishment of support groups, so time will tell how successful a support group structure run by nurses, but inclusive in nature, will be. We believe, however, that inclusiveness is a good thing to work toward, especially in smaller rural areas where communities are traditionally very close-knit. Our initial experiences with inclusive support groups have shown that hospital administration seems to be more inclined to approve and provide support to the establishment and running of such support groups, since it is an intervention that helps all health-care workers, not just an exclusive segment (i.e., nurses) of the workforce.

In Malawi, NONM has become the leading health-care professional agency in the country, organizing more than 2,700 nurses nationwide. From time to time, nurses will support and speak out on behalf of other health-care workers who do not have a strong association backing them. In such a setting, it is a natural to expand local support groups to include other health-care workers, while at the same time not relinquishing nursing control.

**THE WAY FORWARD**

With the experiences gained in Zambia and more recently in Malawi, NNO feels confident that it has developed a process and structure for the establishment of local support groups in resource-limited settings in which ownership and direction are developed and supported by local grassroots activity.

In Zambia, many of the local support groups have established themselves as viable organizational and financial entities. Several of them have sizable bank accounts and are continuing with their income-generating activities as a base for funding support activities. As the project draws to a close, these support groups will continue to function as part of ZUNO. A national network of local support groups within Zambia is an asset for ZUNO, both from an organizational standpoint and as a base for human resource development.

In Malawi, the project is still developing its network of support groups, but already considerable interest is being shown by a number of local groups of nurses who want to develop their own support groups. In Mzimba, in northern Malawi, a local support group has formed and already opened a cafeteria, supplying food and soft drinks to hospital employees, patients, and visiting relatives. Additional support groups are being established, and the issue of orphan support is high on the agenda.
HE PROVISION OF HIV TREATMENT and care in resource-limited settings is expanding rapidly. Health-worker training is one of many factors critical to the rapid scale-up of high-quality care.¹⁻⁶ Large numbers of health workers require HIV training, yet few countries have a comprehensive training plan to guide their training activities, a clear assessment of ongoing training needs, a plan to implement training on a large scale, or adequate funds budgeted for training. In this setting, an extensive variety of HIV-related training programs have sprung up over the past few years. Unfortunately, data measuring their effectiveness are limited, and no consensus exists about what constitutes effective training.

Underlying the looming challenge in health-worker training, most resource-limited countries face a chronic shortage of trained health-care providers; chronic understaffing impedes these countries’ ability to adequately train health workers in HIV care. A variety of factors contribute to this shortage. First, removing physicians and nurses from active clinics for training purposes intensifies the strain on clinical care systems. Second, professional programs for physicians and other health workers are lacking in some countries. For example, several countries in Africa and the Caribbean—including Botswana, Lesotho, Namibia, Swaziland, and the Bahamas—do not have medical schools and must send students outside the country for basic professional training (see http://imed.ecfmg.org; Table 1, next page). Third, the economic crisis in several African countries has affected recruitment of new graduates from medical and nursing schools. Finally, trained workers (and potential recruits) commonly leave the public health sector for better compensation, benefits, working conditions, and job satisfaction found in other sectors and other countries—the “brain drain” phenomenon—further exacerbating the human resource crisis.⁷⁻¹²

Faced with these challenges, and with the rapid pace of HIV treatment expansion, few resource-limited countries have sufficient internal resources to address their health workers’ training needs. As a result, most countries have collaborated with external partners to develop health-care-worker training programs and/or to bring in expatriate specialists to provide training, at least in the initial phase of scale-up. Often, these training efforts are poorly coordinated with national training priorities, lack evidence to support their effectiveness, and are driven largely by foreign partners.
result, many training redundancies exist alongside large unmet training needs.

We gathered information on global HIV training through a thorough review of the published peer-reviewed literature, Internet sites, program reports related to training for HIV treatment in resource-limited countries, a survey of HIV training efforts in countries with a high HIV disease burden, and discussions with appropriate professionals in selected countries. In this chapter, we review challenges and approaches to popular methodologies and applications of clinical HIV training in order to address the question: what is the optimal approach to training the health workforce for an expanding HIV-treatment program in a resource-limited setting?

BACKGROUND

Training Appropriate to the Model of Care

The design of a national health-worker training program to support the expansion of quality HIV treatment should be tightly linked to the way in which HIV care and treatment are delivered in the country. Many national programs, such as those of the Bahamas, Botswana, and Uganda, initiated HIV treatment by following a “vertical” specialty HIV-clinic model in which the majority of HIV treatment is provided by HIV specialists. Training according to this approach targets the creation of multidisciplinary HIV-care teams that provide care predominantly, or exclusively, for patients with HIV.

At the other end of the spectrum is the public health model of care delivery, in which HIV care and treatment are provided by primary health-care providers who are trained in basic aspects of HIV care for adults and children and taught to recognize conditions that warrant referral to a specialized setting. Training in advanced aspects of HIV care is reserved for a small cadre of specialists. A hybrid of these two models occurs when a national program starts its treatment program by following the specialty model but decentralizes HIV services to peripheral facilities as treatment scales up. In this case, HIV care and treatment may be provided in a primary health-care setting by primary care clinicians, or by an HIV-care specialist.

In the vertical model, training in HIV care relies on a highly centralized training program driven by a small group of expert trainers, with a core curriculum that can be quickly and easily updated to keep pace with changes to practice and guidelines, and short intensive trainings for small groups of trainees. Parallel systems are often established for training in laboratory methods, counseling and
patient education, data collection, and pharmacy and supply management. As programs decentralize into a public health model, training decentralizes accordingly. Short, intensive trainings in a central setting become less practical. The cadre of trainers and curricula must be expanded, and systems must be implemented to allow for curricula review, updates, and distribution of continuing medical education (CME) and continuing nursing education (CNE) materials. The World Health Organization’s (WHO’s) Integrated Management of Adult and Adolescent Illness (IMAI) training strategy relies on a set of generic training materials that stress training within the public health model of care delivery and is designed for adaptation to fit the training needs of a particular setting. This approach stresses referral mechanisms, team building, clinical mentoring, and clinical monitoring within the context of both chronic and acute care.16

**Training Decisions amidst a Crisis in Human Resources for Health**

The human-resources-for-health crisis in resource-limited countries is a substantial obstacle to scaling up HIV-treatment programs and is directly relevant to health-workforce training. Neither Mozambique nor Rwanda nor Tanzania, for example, has more than 5 physicians, 43 nurses, or 3 pharmacists for every 100,000 people (Table 2).17 The United States, by comparison, has a density of 256 physicians, 937 nurses, and 88 pharmacists for every 100,000 people.17 Chen et al have linked low national staffing ratios to poorer

Latest available data. Data are from the Global Health Atlas of the World Health Organization.17
health outcomes, and it is likely that this link extends to HIV care.

**Training Tailored to Each Health Sector Cadre**

The HIV health-care workforce includes doctors, clinical officers, nurses, pharmacists, laboratory technicians, phlebotomists, counselors, program managers, data clerks, ancillary staff, and community health workers. The function of each category of health worker depends on the local model of care delivery and is influenced by tradition, legislation, and local regulations. Variation in healthcare-worker roles can be an obstacle to adapting generalized training tools and curricula to a specific setting. A study in the United States found that nurse practitioners and physician assistants who specialize in HIV care provide better care than non-HIV-expert physicians and provide care that is comparable to that of HIV-specialist physicians—a finding that could support the expanded role of nurses and clinical officers in HIV treatment in resource-limited settings.

**Common Challenges**

As noted, many countries lack adequate preservice training institutions for health-care workers and must send clinicians outside the country for professional training. Postgraduate migration to other countries is common, exacerbating the human resource crisis. In a setting where the demand for health workers outweighs the supply available, it can be difficult to entice workers to staff underserved areas, such as rural sites. It can be hard to retain health workers when they themselves may feel the impact of HIV, either through their own infection, for which they may or may not be getting the appropriate treatment, or that of family members. Finally, for busy clinics, it can be a challenge to allocate time to training amid demands that staff time be devoted to patient care.

**DESIGNING A TRAINING PROGRAM**

There is scant evidence to support the effectiveness of one training methodology over another. Below, we present some of the advantages and disadvantages of the predominant training methodologies that have emerged ad hoc in the past few years.

**Preservice Education**

Adding or enhancing relevant coursework during preservice education for health professionals (e.g., medical schools, nursing schools) takes advantage of preexisting programs without taking professionals away from the workplace as trainers or trainees. It helps address health-workforce needs and ensures an adequate skill set among graduating professionals. However, it does not address the needs of those who have already completed their professional education, nor does it provide immediate solutions to urgent needs.

**Didactic Training**

Most training programs have emphasized centralized didactic training as the core training method. Didactic training, delivered as lectures in a classroom setting, is often used to convey large amounts of information at one time. Held in a centralized location, it typically lasts a week or two, and can accommodate large numbers of trainees—requiring fewer trainers and resources than other methods and allowing for standardization of the training’s content. The classroom style is a familiar approach for many trainees, yet the translation of classroom knowledge to clinical practice can be challenging, especially if the curriculum is divorced from the practical circumstances facing trainees or among trainees with limited experience. Trainees may not retain knowledge if it is not immediately applied to clinical practice. And, like all methods that take trainees and trainers away from their workplace, didactic training can temporarily exacerbate the strain on clinical care services.
While some programs send multidisciplinary teams of health workers to didactic trainings, others focus didactic training exclusively on one discipline—such as physician trainings or nurse trainings. Often, workers from one clinic who attend the training are expected to bring the information back to their clinic and train the remaining staff, although this may not always take place.

Training of Trainers
A training-of-trainers methodology is generally implemented when programs wish to provide didactic training at decentralized sites. Groups of health professionals are trained as “experts” and then expected to lead or facilitate future trainings. This approach attempts to expand the pool of trainers and leverage resources to build training capacity. An important downside of this method is the potential dilution of information as trainers get further removed from the original trainer’s expertise and information, which can impact the quality of training and the resulting clinical outcomes. Some trainers may require training in educational methods and pedagogy in addition to training in the management of HIV infection.

Refresher Course
It can be difficult for trainees with limited experience to absorb information from a didactic training. Trainees often benefit from practical experience at their own sites, followed by a refresher course. This affords trainees an opportunity to develop skills, before returning for ongoing training, that may add complexity and build on their classroom and practical experiences. It gives programs an opportunity to provide trainees with updated information and affords trainees the opportunity to solve problems together.

Distance Learning
Using computer-based or video-based technology is another way to train health-care workers in resource-limited settings. This approach allows trainees to remain at their workplace and has the added advantage of reaching a wide, geographically disparate audience with simulated cases that allow providers to test their knowledge without negative consequences to patients. These courses are inherently technology- and resource-intensive—the application of this method may be limited in settings with no access to the Internet—and require a certain degree of comfort with technological applications, but they reduce the need for trainers and allow trainees to move at their own pace.

Off-Site Clerkships (“Attachments”)
Some programs, such as those in Botswana and Kenya, complement didactic courses with opportunities to shadow experienced providers. During these off-site clerkships, or “attachments,” trainees spend a block of time with a mentor at the mentor’s clinical facility, which, ideally, is similar to their home clinic. Trainees gradually assume clinical responsibilities under supervision. The mentored environment allows the trainee to practice a skill with the comfort of having an experienced mentor to address questions and difficulties, and reinforces information provided during the didactic course. If the caseload and experience of the mentor are inadequate, or if the attachment site differs significantly from the practice sites of the trainees, this type of training may be less relevant. Finally, attachments can take trainees away from their jobs for an extended period of time.

On-Site Mentoring (“Preceptorship”)
On-site mentoring, or “preceptorship,” programs typically send experienced HIV-treatment professionals (nationals and/or expatriate health professionals) to sites of less-experienced providers for an extended
THE DEVELOPMENT AND APPLICATION OF A DISTANCE LEARNING TOOL FOR HIV CARE AND TREATMENT

Fransje van der Waals

Health[e]Foundation, the Netherlands

Health[e]Foundation is a not-for-profit organization that focuses on training and educating health-care workers in the care of patients living with HIV by means of a distance-based electronic (e-learning) system. The system, known as HIVeDucation, is an interactive, HIV/AIDS clinical management program that is tailored to the needs of clinicians and other health-care workers in regions severely affected by the HIV epidemic. The program has been designed to equip health-care workers with the practical tools they need to initiate and maintain patients on antiretroviral therapy (ART). The goal of the program is to train a new generation of specialized clinicians and health-care workers who can function as local role models who are capable of informing and advising their colleagues.

Programs are started in each country in collaboration with local stakeholders (e.g., public or private hospitals or other groups, such as research groups or medical schools). The first programs were launched in Thailand and Uganda, since these countries had relatively high computer literacy and had already started offering ART. Once the model proved successful, training was conducted in Mozambique, India, Surinam, Indonesia, and Malawi, followed by Kenya, Tanzania, Senegal, Cameroon, Eastern Europe and Bangladesh.

The HIVeDucation training program has several components, including computer-based clinical training, on-site workshops, and continuing medical education. The program combines computer-based self-study courses, clinical case studies, e-assisted tutoring, on-site workshops, and the creation of peer consultation networks. Electronic PDF files of all treatment guidelines and other relevant literature are provided. Participants are also trained in clinician-patient communication skills, counseling on issues of stigmatization and discrimination, and approaches to adherence education and palliative care by using exercises and role-play. Each workshop is tailored to the specific needs of the participant group.

CONTENT AND FORMAT

The HIVeDucation training program is composed of two main elements:

1. Up-to-date general information on HIV/AIDS, including pathogenesis, presentation and management. International experts write the HIV/AIDS modules and update them on an annual basis.

2. Localized country-specific information, including epidemiology, prevention programs and management guidelines. Modules can be added or removed from the program to provide a country-specific course.
In each country where HIVeDucation runs a training course, the Ministry of Health is asked to provide a country-specific epidemiology module to inform the participants about the local HIV/AIDS epidemic, the specific prevention programs that are being implemented in the country, and country-specific HIV testing and treatment guidelines. Several clinical cases per country have been designed with the assistance of local clinicians so that they reflect local resources and situations.

**TRAINING METHOD**

In developed countries, many continuing medical education (CME) programs for physicians as well as nurses are provided via the Internet in e-learning format (i.e., as computer-based learning programs). Our intention was to develop high-quality training for as many health-care workers in resource-limited settings as possible in a short period of time. We decided to develop an e-learning training tool specifically for health-care workers (HCWs) in the field of HIV/AIDS—not only for doctors and clinical officers, but for nurses, midwives and counselors as well. Distance learning has the advantage that HCWs are trained at the workplace, where they can learn at their own pace and in their own setting. This has a double benefit for the health center in that participants can do their training during the course of daily patient care and they can then instantly implement their newly acquired knowledge.

Since the Internet is not consistently available in every setting, we devised a special software program so that participants are able to work offline (via a USB memory stick) and only connect to the Internet to download and upload information to our server. Participants can connect their personal USB-stick to the Internet automatically when it is available. In the absence of Internet access, the information stays on the USB-stick until a connection is made. When connected, participant test scores (the training program is problem-based) are sent to the HIVeDucation database and emails are sent to the e-tutor. At the same time, participants receive updates and new modules from the server. World-renowned experts in the field, who are all committed to update the content of their module on a yearly basis, have written the modules. All modules contain pre- and post-module questions and results. Several references cited during the course are available as PDF files. Depending on the country where the training is given, modules can be added or removed from the course to provide country-specific information.

**IMPLEMENTATION**

The training program starts off with an on-site “kick-off meeting”. During this meeting, members of the HIVeDucation team introduce the program so that participants can learn about the background of the program and the problem-based learning method, and have the opportunity to practice with a hands-on computer exercise. A virtual “participant portal” is set up for each class so that participants have a customized space on the Internet that serves as a point of reference and a communication conduit throughout the training. After the kick-off meeting, participants undertake the self-study course, which usually takes about 12 weeks.

At the completion of training, an on-site three-day workshop takes place that serves as a final review and reinforcement of the course content. The on-site program is tailored to the
needs of the group and generally includes presentations by local and international experts, as well as people living with HIV.

LESSONS LEARNED

- Training teams of HCWs works well to promote teamwork and improve workflows.
- Conducting training for a group of hospitals in one geographical area promotes future networking.
- Computer illiteracy is no hindrance—learning curves of all groups (with different educational backgrounds as well as computer experience) are similar. For example, we trained midwives over the age of 55 who were proud to become not only computer savvy but also to be more involved in HIV/AIDS care.
- Blended learning (i.e., a combination of on-site and online training) is a must—participants work toward the on-site workshop, with support by email and or cell phones motivating them from a distance. Most participants want to have their computer-based learning finished before the on-site workshop.
- Focus groups are a great method for evaluating and improving the program, as well as for encouraging participants to start communicating with one another. We start all three-day workshops with focus group sessions.
- Teamwork, triage and collaboration within the AIDS care team, as well as the hospital, are oftentimes new and attractive concepts for participants. Certificates and diplomas are very important in most countries. HIVeDucation is nationally acknowledged, which increases participant motivation.

COSTS

The costs associated with distance learning are relatively high due to the high cost of the e-learning platform management system and the servers that support it, as well as production of the “offline” USB stick. We were able to start the program with grants from the Dutch AIDS Fonds, Roche and Gilead. Once the program was developed, it was supported by grants from Cordaid, the Dutch AIDS Fonds, and in 2006 a generous five-year grant was received from

period of time (several days to several months) to offer on-site mentoring. The preceptorship training methodology has the same advantages as attachments and also offers training specifically tailored to the trainee's work situation. Preceptorships can be particularly time-, labor-, and resource-intensive, and can require a large number of skilled mentors. While expatriate mentors are not always knowledgeable about local conditions, language, or policy, and may need to be licensed and/or registered to work as mentors, national mentors are in very short supply because of the human resource crisis and the fledgling nature of treatment programs in resource-limited countries. Most countries currently rely heavily on expatriate preceptors. WHO has developed recommendations for clinical mentoring in resource-limited settings. These guidelines include helpful information on planning, budgeting, and the monitoring and evaluation of a national clinical mentoring system as well as guidance on the selection, training, and preparation of clinical mentors.
the Dutch Government. Even with this support, 35% of program costs have to be covered by other sources. We generally receive a small fixed fee per participant from the in-country training partners, after which health[e]Foundation takes care of all remaining costs, such as kick-off meetings, USB memory sticks, IT support, e-tutors, three-day workshop venue, per diems, and facilitator fees.

FUTURE PROGRAMS

TBeDucation is a new program that is similar to HIVeDucation. It focuses on the management of TB in HIV-infected patients. The program is given to all participants after a three-day workshop. It is not a program aimed at experts in TB, but is suitable for all practitioners who see many HIV/TB co-infections but who, until now, have only been trained in HIV/AIDS.

Pediatric HIVeDucation is developed by the Pediatric European Network for Treatment of AIDS (PENTA) as a collaborative training program. PENTA/ESPID has a distance-based learning program available via the Internet combined with a workshop. It will be adapted for use in Africa and Asia and put on USB memory sticks by the Health[e]Foundation. We aim to deliver the program to as many health-care workers who are connected to both PENTA/ESPID and the Health[e]Foundation, and possibly to an even wider range of HCWs. Plans are to launch it in Thailand, Cameroon, Senegal, and Kenya.

CommuniteDucation is another new development. The program contains basic information in the form of animations, comics, movies, and other multimedia to inform and promote discussions within communities affected by HIV/AIDS. We hope that the program will be used by schools, positive living groups, workplaces, peer educators, and others and facilitated by trained HCWs.

Initial steps have been taken to develop new programs on neglected tropical diseases and malaria.

HIVeDucation is now available in English, Spanish, and Portuguese. Translations into French, Russian, and Chinese are expected to be available soon.

For more information about HIVeDucation, please visit: http://www.healthefoundation.eu.

Consultation

Some programs have developed a consultation system that allows newly trained providers to ask questions of experienced providers through direct phone calls, e-mail, call centers, or frequent site visits by the mentor. Consultation systems provide a support network that builds the confidence of newly trained providers. In Uganda, for example, the AIDS Treatment Information Centre hosts a call center that responds to providers’ treatment questions.21 Similarly, the Prince Leopold Institute of Tropical Medicine has developed an Internet-based program, TELEmedicine, to enable its experienced providers to respond via e-mail to inquiries made by clinicians in resource-limited settings.4 One drawback to a phone or e-mail system of consultation is its reliance on communication technology.

---

Case Conferences
Another way to train providers is through case conferences: regular meetings to discuss complex problems in HIV care and to provide updates on practices or guidelines. Case conferences encourage a team approach to HIV care, help establish a network of HIV-care providers for informal consultation and/or referrals, and can reach a wide audience, especially with advanced Internet-based conferencing software, where it is available.

CME/CNE Programs
CME/CNE programs exist in countries with robust medical associations. Preexisting CME/CNE systems can be used as a vehicle for HIV training but are generally used to supplement a preexisting knowledge base, not to train inexperienced providers.

ESTABLISHING A NATIONAL TRAINING PLAN

Tailoring a National Training Plan to a Program’s Unique Circumstances
When establishing a national training plan, planners should consider their options and the appropriate combination of training methodologies in the context of their program’s unique circumstances, including the size of the population requiring treatment, the care delivery model, the extent of local expertise, the existing public health infrastructure, whether staff to be trained work in urban or rural areas, health-care-worker-to-population ratios, political will, nongovernmental organization involvement, available technology, and resources.

Forecasting Training Needs
Training programs would also benefit greatly from accurate forecasts of the demand for health workers: the number of necessary staff needed immediately, the number of staff needed over time as programs scale up treatment, the number of site locations, and the optimal number and mix of staff at each site. Such forecasts would allow planners to determine the extent to which an investment in hiring and training additional health workers would affect HIV care and the extent to which it is critical to budget- and resource-allocation decisions.

In August 2006, WHO estimated that over four million health workers would be needed in 57 countries to fill the gaps created by health worker shortages. When strategizing how to reach three
and death from HIV infection. Although it can be difficult to implement such solutions in resource-limited settings, some programs have chosen to train two individuals for every position, assigning each to spend half of his or her time at the HIV clinic and half elsewhere in the hospital or clinic. This reduces reliance on one individual, allowing each to miss clinical time without significant disruption. Without a buffer system to replace trained individuals, or the flexibility to train additional staff quickly, unexpected staff shortages create bottlenecks in clinic operation, slowing down the flow of patients and straining other staff. A forward-thinking national training plan will not only anticipate the loss of staff but will also incorporate ways to avoid it. Approaches might include augmenting salaries, recruiting staff to work in their home districts, improving staff-to-patient ratios, and providing adequate supplies.

Additional Considerations

Other considerations to be addressed when designing a training plan include training frequency, technological requirements, training site, the target audience, and content material. Planners should decide whether training sessions will be concentrated or spread out over time, and whether they will rely on technology such as computers, video, and Internet connections. Designers of training plans must consider the optimal components of a training site, for example, proximity to a healthcare facility, an environment similar to what the trainees will experience at their home clinic, or the use of the home clinic itself as the training site. Planners must assess the training previously received by workers and decide whether to train one health cadre at a time or to train multidisciplinary teams together. Content material should match the reality on the ground, reflect local practice, and account for the availability of drugs and diagnostic capabilities.

Anticipating and Taking Steps to Prevent Staff Turnover

Training plans should anticipate common experiences—such as the permanent loss of trained health workers who take more lucrative jobs or burn out, the temporary loss of health workers who take leave or attend trainings, and worker illness
Optimal Model for a National Training Program

There is no single model for a national training program, given the differences among countries and HIV treatment programs. However, the elements mentioned above, such as the model of care delivery, the role of each health-care worker, and the advantages and disadvantages of popular training methodologies in the context of the particular country, are critical considerations for the design of any national training program.

CONTEXTUAL EXAMPLES: LESSONS LEARNED WHILE PLANNING AND IMPLEMENTING TRAINING PROGRAMS

Lesotho

In 2005, the government of Lesotho recognized the need to complement its decentralized national didactic trainings with an on-site clinical mentoring (preceptorship) program. As free antiretroviral drugs and laboratory testing became available and new treatment sites were rapidly added, the government determined that the newly trained staff were not fully confident in their ability to initiate treatment and would benefit from practical on-site teaching and guidance. A clinical mentoring program was established in response, relying mostly on expatriate volunteer expert HIV clinicians. Identified district hospitals received a doctor-and-nurse team for a period of six weeks to six months, depending on the progress of the clinic. As treatment expanded from the district hospitals to rural health centers, nurse mentors were also sent to the surrounding health centers where the training need for nurses was greater. Through consultation, case presentations and review, coaching, and encouragement, but not clinical care, the mentors helped guide their colleagues to clinical competence and confidence in their ability to function independently. In February 2008, after two years of relying on foreign mentors, the Lesotho AIDS Directorate hired five local nurse mentors. The transition to a local model involved extensive training for these clinical mentors, including being paired with an experienced foreign mentor.

The government of Lesotho and its implementation partners learned several lessons in the process of rolling out the clinical mentoring program. The Ministry of Health and Social Welfare (MOHSW), in collaboration with the Clinton Foundation, learned the importance of site preparation and clarification of the clinical mentor’s role prior to the mentor’s arrival. The MOHSW found it important to establish from the outset that the clinical mentors (doctors and nurses) were not there to relieve the workload, but rather to assist the clinic staff to identify barriers to scale-up and possible solutions. Written communication from the Ministry of Health (or comparable authority) to the administration of the facility clearly outlining the roles and responsibilities of the mentors and the local staff can be critical to the success of the program.

The initial barriers to scaling up HIV treatment and care are often facility-based: issues relating to pharmacy, labs, medical records, referral systems, and administrative support. The clinical mentor must be willing and able to work with the staff to design solutions to these problems, as these issues are best dealt with before new patients are enrolled. Once a site starts providing ART, clinical mentors can serve a valuable role in encouraging the local clinicians to communicate to the Ministry of Health the additional challenges they face, such as difficulties with medication or test kit stock-outs, sample transport issues, reporting of lab results, or infrastructure weaknesses.

While regular case reviews and team meetings should be multidisciplinary, the best results of the program in Lesotho came when doctors mentored
may have been trained in PMTCT. In one district with 15 PMTCT sites, 168 nurses, out of a total of 214, had been trained in PMTCT. Yet less than half of those nurses are engaged in any way with pregnant women, and the percentage of women receiving antiretroviral prophylaxis for PMTCT continues to be low. In that same district, no one had received training in pediatric ART or DTC (a provider-initiated testing program). The provincial ART officers and district health management teams continue to urge donors to fund trainings that are targeted to the needs of the district.

An emphasis on effectiveness and efficiency should be stressed; uncoordinated, donor-driven, classroom-only training will rarely be effective and efficient. Trainees should be carefully chosen based on their role within the health-care system. Time and money should not be wasted on training people for roles they will not have. Didactic training should be complemented by on-site support and mentoring. Donors should work closely with the local health-care managers to define training needs and fund them appropriately. Government and donors must work together to determine whether increased training is resulting in improved access to care and quality of care, and use this information to revise and improve training programs.

India
The India HIV/AIDS Nurse Training Program was initiated by the National AIDS Control Organization (NACO) in an effort to improve the knowledge and skill level of nurses employed in government ART center hospitals. The Indian Nursing Council (INC) organized a national consultation on HIV/AIDS nursing and gathered together Indian nursing leaders and educators to design the program, which addressed four questions: What is the current role of the nurse in the care of patients with HIV/AIDS? What is the optimal role of a nurse in this setting? What does a nurse need to know to be
able to function effectively in that role? How can a training program be designed and implemented in order to disseminate the necessary knowledge and develop the clinical skills of Indian nurses?

This expert group submitted its recommendations to the INC and NACO, and they were accepted as the guiding principles of this training project. The International Training and Education Center for HIV (I-TECH) was contracted to design the curriculum according to NACO/INC requirements. A team of Indian nursing faculty served as advisors and provided frequent feedback and suggestions. It was the consensus of this advisory group that all nurse training must be practical and patient-focused. The training program emphasizes the role of the nurse in all aspects of HIV prevention, care, and treatment.

A key component of the program is a review of the nursing assessment process and practical application. After a classroom review and discussion of the nursing assessment of the patient with HIV/AIDS, the trainees are taken to the inpatient unit or ART center to interview and assess a patient under the guidance of an instructor. Nurses are expected to be able to stage a patient, determine whether the patient is eligible for ART, and identify nursing interventions appropriate to that patient. On the last day of the training, the nurses present their patients to the group, allowing trainers to assess how well the trainees have understood the material and can apply it to a real patient.

A lesson learned from the development of the India HIV/AIDS Nurse Training Program is that training programs should be based on the expressed needs of the health-care workers trained. The involvement of Indian nurses in the design of the program and as part of the training team ensured that the training would meet the needs and support the role of nurses in the Indian health-care system. This proved to be much more effective than having a physician, professional educator, or public health expert design the training program without input from nurses. Not including the cadre of health-care worker to be trained in the training design can result in material that is too basic or too complex, inappropriate for the practical role of the health-care worker, uninteresting, or impossible to implement due to infrastructure and resource issues at the local health-care facility. Employing an experienced nurse as the trainer was deemed essential by the expert advisory committee of Indian nurses.

For health-care professionals, in-service training is not about learning a set of facts or skills, but about incorporating new information into an existing practice. The preexisting expertise of the clinician should be the basis for incorporating new knowledge related to the care of patients with HIV/AIDS. Didactic training must include some practical demonstration by the trainee that the material has been understood and can be applied in a clinical setting. Case studies, role plays, and other exercises aimed at demonstrating the trainee’s ability to apply new information in a clinical setting are essential.

China

The Lixin Training Center in rural China is the site of an HIV/AIDS clinical mentorship program for Chinese doctors, jointly sponsored by the Centers for Disease Control and Prevention (CDC) Global AIDS Program and the Clinton Foundation. This program supports China’s Center for Disease Control and Prevention as well as the Anhui Province Bureau of Health and the local Lixin County Bureau of Health. Chinese physicians come to Lixin County, Anhui Province, for three months at a time, for practice-based training with an American HIV clinician and a clinical assistant/translator. The training is a mix of outpatient care, inpatient care, didactic lectures, and a training-of-trainers module in which trainees create and deliver their own presentations.
The Lixin Training Center, the first rural practice-based training center in China, places the training where there is a large volume of patients needing care. Prior to the establishment of the Lixin Training Center, the training centers in China were primarily urban-based, where there were few patients, or didactic in nature. The Lixin training program focuses on practical clinical care in a resource-limited setting, where trainees see patients independently and then are mentored in both inpatient and outpatient settings. Continuity of care and follow-up of patients over time is emphasized. One goal of this program is to create a paradigm shift in Chinese outpatient care from a predominantly acute care model to a primary care / chronic disease management model. As of January 2007, 42 Chinese physicians had been trained. The trainers and trainees have cared for more than 800 HIV-positive patients in Lixin, with more than 400 on antiretrovirals. Following their training, the training center graduates have gone on to treat 1,000 more patients.

This practice-based mentoring approach successfully trained competent HIV clinicians who demonstrated an understanding of the shift in the patient model toward comprehensive care and chronic/longitudinal patient management. Some graduate trainees went back to their local sites and spearheaded ambitious new systems and trained doctors at those local sites, mirroring the Lixin Training Center and multiplying the success of the program.

While some graduate trainees were instrumental in spreading the model back to their home sites, some trainees were not allowed to take positions of local leadership in HIV care and clinical training upon their return home. Implementers learned that consultation with local political and healthcare leadership is crucial to identifying appropriate candidates for training. Also crucial is careful selection of trainees who are motivated to learn and to provide care to HIV-positive patients when they return home.

CONCLUSION

Training a robust health workforce is critical for building sustainable HIV-treatment programs. The care delivery model, the roles played by different types of health workers, the number of workers needing training, resources available for training, and the phase of program development all significantly affect training design and should be considered when deciding how to best train the health workforce in resource-limited countries. Evidence to support these decisions will help policymakers and planners of training programs answer the overarching question: what is the optimal approach to training the health workforce for an expanding HIV-treatment program in a resource-limited setting?

ACKNOWLEDGMENTS

This chapter was adapted from work previously published by Elizabeth McCarthy, Megan O’Brien, and William Rodriguez in PLoS Medicine (McCarthy EA, O’Brien ME, Rodriguez WR. Training and HIV-treatment scale-up: establishing an implementation research agenda. PLoS Med. 2006;3:e304). We are grateful to the Clinton Foundation HIV/AIDS Initiative country teams for providing insight into the national training programs. Some of the ideas presented in this report were discussed at a World Health Organization meeting on clinical mentorship for the care and treatment of HIV/AIDS in June 2005 in Kampala, Uganda, attended by Elizabeth McCarthy.

A
LTHOUGH THE GLOBAL HIV/AIDS response has fallen short of meeting the World Health Organization (WHO) “3 by 5” target of starting 3 million people on antiretroviral therapy (ART) by 2005, the initiative did galvanize an unprecedented global commitment to expand access to HIV care and treatment in low- and middle-income countries. With this commitment came a new emphasis on a public-health response to HIV, as opposed to the previously favored “specialist” approach—an important shift needed to address a devastating generalized epidemic. The “3 by 5” initiative; the President’s Emergency Plan for AIDS Relief; and the Global Fund to Fight AIDS, Tuberculosis and Malaria definitively demonstrated the feasibility of delivering ART in even the most resource-limited settings, cooperating to support programs that did exactly that.1-3 Yet despite the provision of antiretroviral medications (ARVs) becoming more affordable for low- and middle-income countries in recent years, long-term access to this life-sustaining treatment remains limited by the ability of health systems to deliver quality care in a reliable manner to all who need it. Chief among the limitations of these health systems is a lack of sufficient health-care personnel with the training and experience to administer these medications to provide lifelong care at the community level for adults and children living with HIV.

Building capacity within the health systems of communities that face the task of scaling up HIV therapy in settings of high disease prevalence and/or limited resources is a tremendous challenge. This chapter will discuss the development of training programs for health-care personnel to meet this challenge.

PLANNING AND PROGRAM DESIGN
The specific human resource (HR) needs of different countries depend on a number of factors, including the staffing levels within the existing system, the prevalence and geographic distribution of HIV disease in the population, the planned model of service delivery (integrated vs. vertical) for the HIV treatment program, the available personnel, the health-system training capacity, and the financial resources available to support HR needs. Designing an appropriate national training program for health-care personnel to meet the needs of a particular country’s ART scale-up plan will have to take all of these factors into account.
Thus, country-specific planning, based on an assessment of the context in which training is to take place, is the essential first step to a successful HR training program for ART scale-up. Such assessment and planning is typically undertaken by the government health officials tasked with charting the national response to the HIV epidemic. In some cases, expert consultants are brought in with the support of government and nongovernmental aid agencies to assist in this process, particularly in countries where health officials are greatly overstretched and the magnitude of the epidemic requires an emergency response. Inclusion and involvement of all possible stakeholders that may contribute to the overall health system is very important from an early stage in the planning of the scale-up of HIV treatment. Such lifelong care is unlikely to be sustainable as a stand-alone program; thus, integration and communication across programs and between agencies is one of the keys to long-term success.

ASSESSING THE TRAINING CONTEXT
The context in which an HIV treatment program will be developed is very important to the planning and design of the training program for health-care personnel in HIV care. A number of conditions must be considered to ensure that a program will meet the needs of the environment where it is to be implemented. These conditions will be described in this section and include administrative conditions, characteristics of the health system as well as the population it serves, and existing resources for training in general and the HIV treatment program in particular.

Administrative Issues
No public health program can begin without consideration of the administrative environment in which it is to be implemented. The public sector plays a vital role in planning for long-term HIV care, particularly in poverty-stricken areas where the population cannot afford to pay for routine health care.

It is important to assess the attitudes, existing policies, and capacity of the administration responsible for public health when the scale-up of training for HIV care is being planned. What is the distribution of responsibility for health care? Does it fall to local authorities, or is it managed centrally? Where are decisions taken? How are budgets distributed? It may be very well for a central health authority to decide that HIV treatment is a priority, but if the allocation of personnel occurs at the district level, then it is important to involve the district-level decision makers in the planning for the training of personnel.

In addition to ensuring that the appropriate decision makers are involved in the planning process for training scale-up, it is important to know the existing attitudes and policies regarding the diagnosis, care, and treatment of HIV.

Table 1 summarizes these administrative issues.

The answers to these questions will allow for a greater understanding of the framework in which a training program is to be developed. Often, a training program must work to build capacity not only among the health-care workers at the ground level but also among the administrative personnel and systems that will support the ongoing treatment program. The need to build administrative capacity, however, must be balanced against the urgent need in a region to start an HIV care and treatment program, due to the particulars of the epidemic and the availability of resources. There is a necessary tension between the need for rapid HIV treatment scale-up and ensuring that the capacity exists within the system to support ongoing quality HIV care and prevention. One should not be ignored in favor of the other.
Antiretroviral treatment, like the management of any lifelong chronic disease, will require patients to have routine follow-up, with regular access to pharmacy, laboratory, prevention, and social work services. In many resource-limited settings, provision of such services for long-term care has not been seen as a priority. Additional challenges arise because HIV, unlike other chronic diseases such as diabetes and hypertension, can be transmitted to others. And although similar to TB in that it is also transmissible, potentially fatal, and capable of developing resistance to medications, HIV often kills people during their young, most productive years, with devastating impact on populations. Cost-benefit analyses clearly demonstrate the consequences to a nation’s economy of an untreated HIV epidemic. Although recent political

**Health-System Issues**

Antiretroviral treatment, like the management of any lifelong chronic disease, will require patients to have routine follow-up, with regular access to pharmacy, laboratory, prevention, and social work services. In many resource-limited settings, provision of such services for long-term care has not been seen as a priority. Additional challenges arise because HIV, unlike other chronic diseases such as diabetes and hypertension, can be transmitted to others. And although similar to TB in that it is also transmissible, potentially fatal, and capable of developing resistance to medications, HIV often kills people during their young, most productive years, with devastating impact on populations. Cost-benefit analyses clearly demonstrate the consequences to a nation’s economy of an untreated HIV epidemic. Although recent political
developments have allowed most countries to offer universal access to first-line medications for HIV, widespread use of second- and third-line therapy remains economically nonviable. It is in the best interests of a society to prevent the development and transmission of drug-resistant HIV, and to implement HIV treatment properly, if it chooses to undertake ART scale-up.

Planning for lifelong treatment of HIV infection must consider issues of sustainability and ongoing access to treatment services. Thus, it is important to examine the existing public-health infrastructure and the challenges to chronic disease management within the current system. A thorough assessment of the current adequacy of staffing levels, diagnostics and supplies management, and incorporation of the chronic care model in the existing system for the care of other chronic diseases, such as diabetes, will give an indication of the training needs to make ART scale-up possible.

These issues are summarized in Table 2.

The primary purpose of an evaluation posing these questions (see Tables 1 and 2) is to determine whether patients who start ART will be able to have ongoing access to uninterrupted care within the existing system. For training purposes,

</table>
it is important to be sure that health-care workers are given training in ART that is appropriate for the level of health-care system in which they will work. This assurance is the key to combating “training fatigue” among overextended workers. Training fatigue often occurs when workers are called away from their duties for a generic training program only to find that they are unable to implement these generic strategies in their current work environment.

Patient Population Issues
A solid understanding of the population served by an HIV treatment program will inform the tailoring of the training program to ensure maximum relevance to trainees. Information regarding the epidemiology of HIV in the country will help define the populations that will need treatment and thus the services that will be most needed. For instance, it is important to determine how much of the epidemic is focused among the poor, who will need access to public sector services and nutritional support; whether patients are concentrated in rural or urban areas; and whether levels of literacy will allow written health-promotion materials to be used and in what languages materials should be developed. It is also important to know the prevalence and incidence of HIV among women of childbearing age and the availability of perinatal services, as well as the HIV prevalence and incidence in children, as all of these factors will shape the design of an HIV treatment program. The presence of a concentrated epidemic among disenfranchised members of the community, such as injecting drug users (IDUs) and sex workers, will require that the training program address services specific to the needs of these populations. Finally, it will be important to learn about the epidemiology of comorbid conditions and opportunistic infections (OIs).

HIV-Specific Issues
Often, the scale-up of HIV-related services will take place in an environment where work has already begun in tackling the epidemic. Learning about the existing programs, the groups and individuals working on them, the extent of what has been tried, and the challenges faced will be very helpful in preventing duplication, engaging potential allies, and avoiding conflicts in the planning of a training program to build capacity for ART scale-up. These issues are presented in Table 4.

Gathering information on all of the topics enumerated in the preceding sections will allow for a solid foundation for the design of a program of large-scale training to support the nationwide scale-up of HIV treatment.

MODELS FOR SCALE-UP OF TRAINING IN HIV TREATMENT SETTINGS

Centralized Training Models

Centralized training for centralized treatment programs (i.e., vertical program or specialist model). Training can eventually become more decentralized, with training and clinical rotations for trainees taking place at the main site. This model is appropriate for settings with relatively low HIV prevalence, sufficient infrastructure and resources for patient transport, limited available personnel, and/or sufficient communications and medical records infrastructure for patient tracking.

Centralized training at a central treatment site using the team approach. This approach involves bringing a multicadre team from new sites to a central training hub, followed by on-site expert preceptorships to facilitate the launch of the program at new sites (i.e., vertical program). This is appropriate for settings with very high HIV prevalence, ample human resources, and well-supported programs that are able to fund the
extended training of health-care workers hired only for the treatment program, as well as transport, accommodation, and salaries of external experts for on-site precepting.

**Decentralized Training Models**

**Decentralized training with ongoing mentorship.** In this train-the-trainers model, a team of health-care professionals consisting of members from each cadre of an ART care team come to a central training site from regions where the program is to be rolled out. They are trained in ART care, how to train colleagues in ART care, and the specific features of the national program. Training is in the form of workshops that combine didactic with experiential learning. After attending the workshops, trainers return to their regions to conduct local trainings for scale-up of the ART program. This model is usually supported with ongoing mentorship by the central training team and external experts.

This model is appropriate for settings with a high burden of HIV, a significant shortage of human resources, the need to integrate the program into existing services, and/or the need for training that requires minimal travel and missed workdays.

**Decentralized in-service training using a facility-based team approach.** In this model, a designated care team at each facility is trained by a team of experts, who conduct the training through a series of on-site, in-service workshops. These consist of didactic and case-based learning, followed by a visit to an established site to observe hospital-based care. This model is appropriate for settings with a large population, relatively low HIV prevalence, many public health-care facilities over a large geographic area, or where there is a need for widespread scale-up to established facilities.

**Decentralized training using ongoing distance-learning workshops.** This model involves the delivery of didactic lectures and case-based learning to a wide number of health-care professionals of varying cadres using telecommunications technology. This is appropriate for settings with high HIV prevalence, a widely dispersed population, poor infrastructure for transport of patients, adequate existing decentralized health services, and a suitable communications infrastructure to support teleconferencing.

FROM THE GROUND UP: LAYING A STRONG FOUNDATION

provide technical consultants for the development of treatment guidelines.

Vertical vs. Integrated Programs
It is rare to have sufficient numbers of staff to create a stand-alone HIV program (also known as a vertical or parallel program). In most developing countries, the best alternative is to build on any existing infrastructure of decentralization.

Central-Level Capacity Building
In some settings, a comprehensive training program for the roll-out of ART will have to include education, training, or capacity building at the central or administrative level. This may take the form of policymaker education workshops, assistance in guidelines development, or the seconding of staff within the administration for the management of the program. Some examples of where this has been done successfully include Botswana, where staff were seconded to the government by African Comprehensive HIV/AIDS Partnerships (ACHAP) for program development; Lesotho, where consultants from the Clinton Foundation and WHO worked with the HIV/AIDS directorate to outline the program and successfully apply for funding; and India, where the Centers for Disease Control and Prevention (CDC) and the Clinton Foundation support administrative staff positions within the national AIDS program and the clinic from remote locations when needed. The program also became a center for preservice training of physicians and nurses. Over time, as enrollment has grown, the program has been able to decentralize to provide HIV care at remote primary-care sites. Staff are trained centrally via workshops coordinated by the Caribbean HIV AIDS Regional Training Network and overseen by the central program staff. Clinicians are trained with clinical rotations at the original clinic (some have received prior preservice training at the main clinic).

ADDED CONSIDERATIONS FOR PROGRAM DESIGN

Preservice Training
Because of the high rates of attrition of healthcare professionals in many developing countries, vacant positions will often be filled by new graduates. Thus, it is important to ensure that HIV pathogenesis and treatment are well covered in nursing and medical schools, as well as orientation to referral and reporting systems used within the program. However, this is worth prioritizing within the training roll-out only if there is a solid strategy for recruitment and retention of graduates and if the jobs are funded and available within the program.

SAMPLE TRAINING MODEL: BAHAMAS

The HIV treatment program was begun in Nassau with a single, very motivated physician and his staff. The initial training of the main physician was undertaken at his own initiative, with the help of experts outside the country. This physician became proficient in the care of both adults and children living with HIV and then undertook training of his own staff and sought support for the program. The program employed an aggressive system of contact tracing and adherence support as well as securing funding to assist patients with transport to the clinic from remote locations when needed. The program also became a center for preservice training of physicians and nurses. Over time, as enrollment has grown, the program has been able to decentralize to provide HIV care at remote primary-care sites. Staff are trained centrally via workshops coordinated by the Caribbean HIV AIDS Regional Training Network and overseen by the central program staff. Clinicians are trained with clinical rotations at the original clinic (some have received prior preservice training at the main clinic).
SAMPLE TRAINING MODEL: BOTSWANA

Botswana’s national HIV treatment program, MASA, began with the establishment of a state-of-the-art treatment facility in the nation’s capital. The treatment model is based on the hospital as a “fixed-capacity multiplier,” able to initiate care and stabilize patients, with patients continuing follow-up at four satellite clinics. Health-care personnel are trained with a series of didactic workshops using the KITSO (Knowledge, Innovation, and Training Shall Overcome AIDS) program, followed by shadowing of the clinicians in the central clinic sites (medical doctors, four weeks; nurses and laboratory personnel, two weeks). Satellite clinic staff must pass a test before their facility can be certified as a treatment site. Once ready to open a peripheral site, staff are joined by international consultants brought in by African Comprehensive HIV/AIDS Partnerships (a collaboration between the government of Botswana, the Bill and Melinda Gates Foundation, and Merck), who then remain for three to six months to oversee the local team in running the clinic and treating patients.

(e.g., TB DOTS [directly observed therapy short course] and antenatal care programs) and train the personnel in these programs for appropriate HIV-related care. For example, TB DOTS workers can also be trained for adherence support in HIV treatment, and both DOTS workers and antenatal care workers can be trained as important resources for prevention counseling and HIV screening in the community. This approach also helps to reduce stigma by demystifying HIV care. In other words, HIV is not singled out and set apart from other diseases, as is common in vertical programs.

Testing and Counseling
Recent years have seen tremendous progress in “know your status” campaigns. Building seamless links between treatment programs and testing programs is essential to increasing treatment access and providing added motivation for the public to get tested. It would be unethical to provide testing without linking individuals who test positive to appropriate care and support.

Social Services
Because HIV treatment is lifelong, any treatment program must take into account the social-service issues that may present obstacles to ongoing care for patients. A comprehensive training program should include training for social work personnel in HIV-related issues and should highlight services that exist within the program and the larger community.

Prevention Services
The advantages of combining HIV transmission prevention with the provision of ART are many. Because patients will be in regular contact with their treatment providers, there will be many opportunities to educate them and reinforce the need for protection to prevent reinfection or the infection of others. Training on prevention counseling (including “prevention for positives”) and supply management for support of prevention strategies (e.g., condom use, family planning, deliberate safe conception) should be included in the training of personnel in ART clinics.
Prescribing and Dispensing
Different health-care systems may have varying regulations regarding prescribing and dispensing medication. This must be taken into account when considering the task sharing of personnel for ARV provision and the respective training needed for the different cadres. Additionally, some training of management personnel may also be needed to facilitate the understanding and planning needed to ensure uninterrupted supplies of medications to dispensing sites within the program.

Chronic Care
Monitoring ART, diagnosis and management of OIs, monitoring for and prevention of complications, and prevention of secondary transmission are all required for the ongoing management of stable HIV infection. Long-term chronic care will need to be undertaken at the primary care level, and consideration must be given to training and other needs related to the sustainable provision of chronic care at this health service level.

Laboratory Capacity Building and Sample Transport
Chronic management of HIV will require regular monitoring of basic laboratory tests, including CD4 lymphocyte count, according to the schedule set forth in the treatment guidelines. Decisions regarding task shifting and decentralization of care will have to take into account the feasibility of providing laboratory services at varying levels of the health system. The training program may be called upon to include the training of laboratory personnel as well as the training of all cadres in the standardized plans for sample collection, transport, and reporting.

Referral Systems and Communications for Consultation and Mentorship
The cornerstone of any decentralized program is a reliable system of communication for referral and consultation. The lifelong management of patients on ART will require health-care systems to devise strategies of decentralization and task shifting so that stable patients can be managed as close to home as possible without compromising the quality of care. The training of lower cadres of health-care workers will need to emphasize when to call for advice or assistance, and it is important that such mentorship be dependably available when needed. The training of all cadres should include training in the referral system, including the roles and responsibilities of personnel at each level. Also, it is recommended that individuals who will be at the higher levels of the referral chain be included in the training as content consultants and training facilitators.

**SAMPLE TRAINING MODEL: LESOTHO**

The government of Lesotho collaborated with WHO’s Integrated Management of Adult/Adolescent Infection program for its initial program scale-up. Training of trainers was performed over two weeks and comprised a number of didactic and interactive sessions by international experts and local people living with HIV, plus hospital-based clinical training. Trainers then returned to their sites and trained fellow workers in the program, supported by the central HIV/AIDS directorate. Ongoing clinical mentorship has been provided by international HIV clinicians supported by the International Center for Equal Healthcare Access and the Clinton Foundation.
WORKFORCE CAPACITY

Sample Training Model: India

India's National AIDS Control Organization (NACO) has recently begun the large task of scaling up the country's AIDS treatment program from a relatively small number of sites in large urban hospitals to planning for the roll-out of a standardized program of care in all states. Together with the assistance of experts from WHO, CDC, International Training and Education Center on HIV (I-TECH), and the Clinton Foundation, NACO has developed a curriculum for training personnel to establish ART sites at public hospitals throughout the country. The curriculum engages personnel from clinician and nursing cadres and offers education and training for administrators in the national program.

Record Keeping and Data Management

As with any chronic disease, HIV management requires that a provider be able to follow a patient’s progress over time and that good records be kept of the history of the illness for that individual. In many resource-constrained settings, most health care is provided on an acute basis; thus, the idea of keeping durable patient records is relatively uncommon. A challenge for HIV training programs is to introduce and reinforce the importance of chronic health maintenance and the use of written and electronic patient records to guide management. It is a very practical and useful strategy to have standardized forms for recording patient-level information, as well as facility-level information, and to include training on the use of those forms in the training of personnel for HIV care.

Evaluation Plan

Because of the public-health implications of HIV treatment resistance, maintaining quality of care in resource-limited settings takes on great importance. Thus, monitoring and periodic evaluation of program quality must be included in plans for training. This planning will require agreement of stakeholders (funding and implementing partners) on desired outcomes of the program, indicators to be measured, intervals for evaluation, and plans for addressing the findings of an evaluation. It is helpful to include plans for evaluation in the development of the training program so that elements of monitoring and data collection can be included in the training of management and administrative personnel as well as guiding the training content.

The Case for Careful Planning

Effective antiretroviral treatment, like the management of any lifelong chronic disease, will require patients to have routine follow-up, with regular access to pharmacy, laboratory, prevention, and social work services. In many resource-constrained countries, provision of such services for the long-term care of chronic disease has not been an economic priority. But long-term care of HIV, as explained previously, poses a particular challenge in that HIV can be transmitted to others, even by those without symptoms or on treatment, and when individuals do not have regular access to services, resistance to medications can develop and such resistance can be transmitted. The implications of this for planning treatment programs cannot be overstated. Using sub-Saharan Africa as an example, experts say that for every individual who was placed on anti-AIDS drugs last year, five more were newly infected, and the region’s rate of new infections has not improved since the late 1990s.
The specter of drug-resistant HIV looms large in this part of the world, where second- and third-line treatments will be much less feasible to provide to large numbers. It is in the best interests of a society to prevent the development and transmission of drug-resistant HIV, and to implement HIV treatment properly if the decision is made to undertake ART scale-up.

In recent years, tremendous progress has been made in improving access to HIV treatment in developing countries. For example, 28% of those in need of ART in sub-Saharan Africa were receiving it in 2007, compared with just 2% in 2003. There is currently great donor interest in global HIV programming, resulting in many organizations having much to offer to advance the goal of increased access to HIV treatment. Efforts that assist in bringing quality HIV care to existing health systems must often face the fact that these systems are severely lacking in resources for other basic health services. This situation can be extremely challenging, as these shortages must be taken into account and addressed before new services are scaled up. Although the severity of the HIV epidemic brings urgency to the cause, there is still a need for careful planning and consideration of all variables to ensure the long-term success of new or expanded HIV care programs. There is also a need to integrate HIV care with other existing services (e.g., TB, antenatal clinic [ANC]) whenever possible so that available health-care resources are used efficiently.

**INTERVENTIONS FOR TRAINING SCALE-UP**

**Promoting Local Ownership: Policymaker Education and Guideline Development**

Local ownership of a training scale-up program is essential for its success and long-term sustainability, particularly if the program is being initiated and supported by an external international organization. Ownership and “buy-in” may come from the central government as well as local health-care administrators involved in the implementation of the treatment program. Interventions to promote local ownership should be based on an assessment of the administrative conditions in which the training program is to take place (see Table 1). These interventions may take the form of high-level meetings, frank discussions with important community leaders and policymakers about the challenges of the HIV epidemic and the need for training scale-up, workshops with members of various departments and nongovernmental organizations (NGOs) to develop strategies.
and plans, or even “education tours” for key officials of successful HIV treatment programs to give them an idea of what is possible in their region.

Guideline development or revision may also be undertaken at this time. This should be done with input from local experts as well as international technical advisors. Local experts are a tremendous resource for understanding the particular characteristics of the epidemic in their region and for information on drug and diagnostics availability. Local experts can also provide key insights into the population to be served. For these reasons, their early engagement in the development of the training content is vital. International technical advisors bring their knowledge from years of practice using ART for chronic HIV care and experience with the evolving epidemic.

Systematically Evaluating the Existing Health-Care System

With the cooperation and participation of local counterparts, the next step in planning a nationwide training program to support ART scale-up is a formal evaluation of the existing health-care system by those designing the training program (whether local government officials or external expert consultants), with a focus on training needs for ART scale-up (see Table 5). This evaluation should extend to all levels of the health system that will be required for quality long-term HIV care and include the input of national, regional, and district health authorities as appropriate.

The outcome of this evaluation may form the basis of a report to local stakeholders and policymakers regarding the identified training needs and the proposed design of the training program. The design of the training program should also be informed by the broader assessment of existing access to care described in the previous section. Often, the details of the ART program design are worked out in this process, bringing the planning more in line with on-the-ground realities, such as staffing and laboratory capacity. A common example of this is when policymakers have initially planned for a vertical program of HIV care but come to realize that staffing constraints will not support a stand-alone HIV program.

Designing the Plan for Training Scale-Up

A training program for health-system personnel in HIV care is not possible without a well-considered national plan for the sustainable delivery of chronic HIV care. This plan should be clearly elucidated in a guideline or policy drawn up by the responsible policymakers. The plan should map out the responsibility for HIV care at the various levels of the health-care system as well as plans for the budgetary and systematic support of care at each level. The capacity for HIV care at various levels of the health-care system will dictate the training content appropriate for different cadres of workers at the different levels. However, the treatment plan does not necessarily indicate the way that this systemwide training of health-care personnel should be carried out.

There are a number of models that may be used to approach the national scale-up of training for a new HIV treatment program. These models, centralized and decentralized, were explained and examples given in the previous section. In choosing among these models, the best approach will be determined by the number and distribution of personnel to be trained, as well as by how the system can best accommodate the large-scale training of staff. For example, in areas with severe HR shortages, staff to be trained may not be able to take time away from existing duties to travel to a central training site and/or may be limited in the amount of time available at a stretch. In other cases, staffing numbers may be less of a problem than the urgent need to get training completed quickly; thus, a shorter-duration, more centralized approach may be advised.
## Table 5. Training Considerations for Specific Health-System Components

<table>
<thead>
<tr>
<th>Health-System Component</th>
<th>Considerations</th>
<th>Implications for Training</th>
</tr>
</thead>
</table>
| **Administration**      | ■ Capacity to acquire and administer funding within the system  
■ Policies in place  
■ Accountability | ■ Training needed for administrators, seconding of staff  
■ Workshops/education/guidelines development  
■ M&E plan, indicators, and outcomes |
| **Staffing**            | ■ Feasible distribution of tasks for ART provision: by cadre, level of health system  
■ Numbers: staffing levels, attrition, labor pool/supply  
■ Prior training or experience with HIV (disease burden at sites)  
■ Existing positions for necessary staff (e.g., counselors, data clerks) | ■ Availability of varying levels of trained staff will influence ART treatment program design and ultimately training program content  
■ Availability of staff for training, utility of preservice emphasis, incentives, certifications, promotion opportunities  
■ “Training fatigue,” relevance of content |
| **Care model: acute vs. chronic** | ■ Capacity for acute care: diagnostics, drugs, equipment at various levels  
■ Capacity for chronic care: medical records, communications, staffing, supplies | ■ Identify areas of strengthening needed to provide adequate acute and chronic aspects of ART  
■ Will influence planning for distribution of tasks within HIV care and content of training |
| **Supply management**   | ■ Adequate staffing at various levels | ■ Training needed to ensure stable supply of ART drugs and diagnostics |
| **Communications: capacity for referral and consultation** | ■ Adequate transfer of patients and information between various levels of system | ■ Training on systems and procedures for referral/consultation at each level is a significant element of training |
| **Medical records systems** | ■ Maintenance of confidential individual records  
■ Adequate reporting between levels of the system (inpatient, lab, pharmacy)  
■ Capacity for collecting monitoring data | ■ Training on medical records systems is a significant element of training program at each level |
| **Monitoring and evaluation (M&E)** | ■ Challenges to existing reporting  
■ Capacity for data management  
■ Use of information: feedback/follow-up | ■ Training in monitoring tools and data collection are a significant element of training program at each level  
■ Plan for ongoing mentorship based on findings of M&E |
Adapting and Developing the Training Curriculum

Just as the training model must be specific to the needs of the health system in which the staff are being trained, so should the training content be adapted for the needs of the program. Bearing that in mind, some essential topics may be considered core elements of a curriculum in HIV treatment scale-up. The specific training content for each cadre at the respective levels of the health system will vary, with the following key concepts composing a minimum basic knowledge set to be covered by the training program as a whole.

- **Epidemiology.** This should include the epidemic today, such as global, regional, and national figures for adults (men and women) and children living with HIV; people newly diagnosed with HIV; and HIV-related deaths (as per Joint United Nations Program on HIV/AIDS [UNAIDS]). The known history of the HIV epidemic in the local context is also useful.

- **Basics of HIV.** This should include the essentials of the human immune system, HIV life cycle, and natural history and progression of the disease.

- **Reducing HIV transmission.** This can include the clinician’s role in prevention through education, diagnosis and treatment of sexually transmitted infections (STIs), preventing and managing occupational exposure, and case detection of asymptomatic HIV (including during pregnancy), with referral for prevention of parent-to-child transmission (PPTCT) and neonatal prophylaxis.

- **Recognizing and testing for HIV.** This can include elements of testing and counseling, test specifics, and explanation of the window period.

- **Presentations of HIV.** This can include case recognition, sexual history taking, and details of OI diagnosis and treatment.

- **ART.** This can include how and why drugs work, goals of therapy, introduction to principles of resistance, availability of ART drugs in the local context, national protocol for ART (including guidelines for pregnancy and TB), drug reactions and interactions, routine monitoring, adherence support, and identifying clinical, virologic, and immunologic failure.

- **OIs.** This can include prevention, prophylaxis, and recognition and syndromic management of major and minor OIs according to national guidelines and available resources.

- **Pediatric HIV.** This can include prevention, recognition, diagnosis, and management of pediatric infection per national guidelines, with discussion of breastfeeding, immunization, and diagnostic and pharmaceutical resources available.

- **Orientation to services provided under the new program.** Services may include voluntary counseling and testing, PPTCT, ART, OI treatment, and laboratory services. Understanding of consultation and referral systems should also be discussed.

Developing Training Materials

Once a plan has been designed for the scale-up of the training program, materials must be developed and reproduced in adequate numbers. The content of the training with regard to medication choices, service provision, and clinical and lab monitoring of HIV should be dictated by the country’s HIV treatment guidelines. A variety of different materials will be developed for a comprehensive, systemwide training program, and it is important to consider all of these in planning and budgeting for training.

The following are important considerations to be made when planning and designing training materials.
Use of Training Materials as References

It is useful to consider what elements of the training content will be most essential to ongoing everyday implementation of the treatment program and to consider creative ways to make the information useful as a reference. For instance, books or binders are useful references when they contain details of protocols, clinical descriptions and photographs, and/or medication information and equipment specifications. Posters and wall charts can also prove useful to help trainees implement the new knowledge they have acquired. These job aids may present algorithms, regimens, emergency protocols, or patient education outlines. Pocket manuals can be useful for easy reference to important lists, formulas, contact numbers, treatment and diagnostic algorithms, and dosing information. CD-ROMs can be given out during or after training for the provision of reference literature, digital images, and self-guided refresher courses. Finally, Web sites can be developed for the provision of clinical, educational, and research updates, medication specifications, and diagnostics information.

Developing Evaluation Materials

Based on the agreed-upon goals and indicators to be measured in evaluating the HIV treatment program and the corresponding health-care worker training program, materials must be developed for use during and after the training. These materials may include some or all of the following:

- Training program evaluation
- Registration forms for recording demographics of participants
- Baseline knowledge (pretest) and current practice surveys
- Course satisfaction forms
- Knowledge posttests
- Treatment program evaluations (to train participants for ART program data collection)
• Patient information forms
• Registers
• Referral forms
• Laboratory forms
• Reporting forms

Training Roll-Out
After thorough planning and preparation, implementation should proceed according to the training model developed. The training model, as discussed earlier, refers to the physical location (centralized or decentralized) and mode of information delivery, as well as the groupings and order in which all health-care workers will pass through the program. Given the HR constraints of most countries rolling out ART scale-up programs, care must be taken in planning trainings to ensure that all staff are able to be trained in sequence while not depleting the sites of staff during training.

Recommended approaches include the following:

• **Training by team.** Teams from several sites that include a representative of each cadre are sent sequentially for workshop-style training at a regional training location until the full staff of each institution has been trained.

• **Training by cadre.** In-service trainings are conducted for groups of each cadre over a relatively long period of time rather than in an intensive workshop setting.

• **Training by institution.** This approach is typically used during institution-based in-service trainings, rotating through small groups over a longer period of time. Stakeholders or funders sometimes require this type of training for proof of feasibility or justification of budget. In cases of disagreement between stakeholders on policy issues (e.g., feasibility of sample transport strategy, need for supply-chain management, acceptability of routine testing strategy), a pilot can allow data to be collected to guide possible revision of the national plan as indicated. Where serious discrepancies exist between regions in infrastructure or HR capacity, staged roll-out can allow for needed capacity building.

**IMPLEMENTING HIV TREATMENT PROGRAMS**

The work of the training program does not end with the completion of training and the start of implementation of the treatment program. Once training has been completed, the scale-up of the HIV program can begin. This entails not only beginning to provide HIV treatment with ARVs but also to implement the program to supervise trainees and to collect data for monitoring and evaluation, all of which have implications for the training program. Activities that are needed after the conclusion of training include the following:

• **Initiation of the HIV care program.** It is generally recommended that this take place as soon as possible after completion of the training. Often, there are logistic or systematic constraints that impede the initiation of care at the site, underlining the importance of close collaboration with administrators and the inclusion of central-level capacity building in a training program.

• **Supportive supervision and mentorship.** The training program should include plans for ongoing supportive supervision of trainees as they begin to implement the program. Some programs (such as Botswana's MASA) have international expert mentors on-site for the initial weeks of ART provision. Others have close supervision by the experts from the local referral center. It is recommended that a long-term, ongoing program of routine clinical mentorship be planned, with a built-in mechanism for feedback and supplemental training as needed to maintain program quality.
• **Data collection.** Roll-out of the program should mark the start of data collection for the ongoing monitoring of the ART program. The early days of the program are the essential time for data consultants and information technology experts to note and correct any problems in these systems.

**Evaluating Training**

Donald Kirkpatrick has described a framework for evaluating professional training development programs. Kirkpatrick’s model, which has been used as the basis for evaluating the Health Resources and Service Administration’s AIDS Education and Training Center, comprises four measurement levels:

- Participants’ reaction to the training, surveyed at the conclusion of the training and six months later, measuring satisfaction and comfort with preparation for treatment provision
- Learning—improvement in knowledge of HIV pathogenesis, treatment, and the program—measured before and after the training and at six months
- Changes in behavior that result from the training assessment of clinical practice performed by mentors at the treatment site
- Final results of the training—improved access to care, satisfactory clinical treatment outcomes, and improvement in the standard of care as measured by the patient monitoring system and the indicators monitored for the evaluation of the treatment program

This is just one suggested framework for analyzing the data collected during the training program and implementation of the HIV treatment program. It will also be important to return to the statement of goals established for the training program at its outset and analyze the measured indicators accordingly.

**Feedback, Revision, and Follow-Up Training**

Following the evaluation of the training program, an important next step is to address the findings of the analysis. Monitoring and evaluation provide a valuable opportunity to discover areas where supplemental training is needed or aspects of the training program that need revision before further scale-up. These activities include the following:

- **Postpilot revision or staged scale-up.** Typically, the time frame of evaluation is short, not allowing for analysis of clinical outcomes but rather focusing on operational issues of the training program and implementation logistics. Information gained can be used to generate recommendations for revision of the program before implementing further.

- **Ongoing continuing medical education (CME).** Weaknesses revealed through analysis of monitoring and evaluation data can be used to formulate a program of ongoing CME for providers and possibly can reveal the need for further education of administrators and policymakers.

- **Mentorship.** A solid program of mentorship should provide the opportunity for mentors to give individual-level feedback to their mentees and to foster them in their ongoing professional development. Such relationships contribute greatly to the strength of the care network and the success of the referral and consultation system.

- **Stakeholder reports.** Good data collection, analysis, and evaluation allow a program to demonstrate to funders and other stakeholders what they have accomplished through the training program. Good monitoring and evaluation is a useful tool to make the case for next steps and subsequent program needs.
TRAINING AND TREATING AT THE SAME TIME: EXPERIENCES WITH NATIONAL HIV/AIDS TRAINING IN NIGERIA

James C. Shepherd, Abdulrazaq Habib, and Patrick Dakum

Institute of Human Virology, Nigeria

NIGERIA, UNLIKE MANY OTHER countries in sub-Saharan Africa, is fortunate to have a large number of doctors and nurses graduating from local institutions. However, at the start of the rapid expansion phase of the President's Emergency Plan for AIDS Relief (PEPFAR)-supported treatment effort in Nigeria in 2004, there were very few locally active clinicians with in-depth experience managing patients living with HIV. At that time, HIV and AIDS had yet to become a focus of the country’s medical school curriculum.

In early 2005, the PEPFAR-supported University of Maryland Institute of Human Virology ACTION (AIDS Care & Treatment in Nigeria) program began the rapid scale-up of HIV/AIDS treatment services throughout the country. As the single largest supporter of ART services in Nigeria, the ACTION program urgently needed to develop a core group of clinicians knowledgeable in the treatment of HIV infection, as well as related complications. At first, a basic curriculuma was used and teachers were flown to the capital, Abuja, from academic medical centers in the United States to teach the five-day course. Approximately 60 doctors, nurses, and pharmacists representing five large Nigerian government teaching hospitals were trained in the first two trainings. The course covered the basics of HIV pathophysiology, the WHO first-line ARV pharmacopeia, adherence issues, toxicities, and opportunistic infection diagnosis and management. At the completion of the first round of training, medical officers initiated the ACTION program’s first patients on ART, in March 2005.

Subsequent five-day introductory trainings were conducted as the program expanded into new centers and required new clinical staff as well as replacements for staff who transferred out of the program. The curriculum was modified each time it was taught to reflect the realities faced by participants in their local settings.

Program staff soon realized that a five-day introduction to the basic concepts of HIV/
AIDS medicine was insufficient preparation for clinicians who needed to manage severely immunosuppressed patients and prescribe complicated drug regimens. For instance, although the course covered ART failure and some fundamentals of protease inhibitor–based therapy, it became apparent that physicians were reluctant to begin second-line treatment, even when faced with clear cases of treatment failure.

Follow-up training, including more intensive supervision and confidence building, was obviously needed but the task was daunting. How could the program train a nationwide network of providers in a country more than twice the size of California with very limited expert personnel? A preceptor program using clinical experts from outside Nigeria to mentor newly trained Nigerian clinicians was then developed based on models of successful programs from other settings. To recruit experts from abroad, advertisements were placed on the Web sites of the Infectious Diseases Society of America and the British HIV Association for experienced board-certified physicians with an active practice in AIDS management who were prepared to come to Nigeria for one to six months.

The preceptor program includes a mixture of classroom didactic training followed by case-based learning. Several physicians from a variety of countries have participated in the program since its inception and have provided valuable mentoring and case-based instruction. At the end of 2007, the ACTION program had provided ART to 42,000 patients, and clinicians were gradually becoming more confident in the management of complex conditions, such as treatment failure. In fact, graduates of the program have begun to train their colleagues within their network of ART sites, setting up trainings at the tertiary “hubs” and inviting providers from the secondary and primary “spokes.” In addition, the Nigerian government is promoting a WHO-sponsored short course in AIDS management throughout the country.

Efforts are now under way to increase the amount of HIV/AIDS management instruction contained in the undergraduate and postgraduate curricula of Nigerian medical schools and medical credentialing societies. It is hoped that this will help establish a career path for clinicians interested in the field of HIV/AIDS. Development of a national program of medical knowledge assessment will then be necessary to ensure a basic minimum standard for providers of HIV/AIDS care. It is expected that these measures, coupled with increased investment in public services, may lead to a strengthening of morale in the public sector and a consequent increase in commitment to the provision of quality HIV/AIDS care and treatment services throughout the country.

B OTSWANA, A SOUTHERN AFRICAN country of 1.7 million people, is among the countries most severely affected by the AIDS pandemic. In 2001, in the face of the growing threat posed by HIV—identified by former president Festus Mogae as a national crisis—the government of Botswana announced that it would provide antiretroviral therapy (ART) free of charge to eligible patients. This initiative, at the time without precedent in Africa, posed significant challenges to Botswana’s already overburdened public health-care system, especially in terms of the additional demands this would place on health-care personnel, infrastructure, and training programs. In spite of these challenges, the government of Botswana responded to the emergency by introducing a national ART program in January 2002.1

The lack of trained medical personnel, identified early on as a key challenge, continues to be a major obstacle to the timely and effective rollout of ART programs in Botswana and other African countries.2–6 Unlike high-income countries with low HIV prevalence, where HIV care is often provided by specialists, most African nations must marshal their entire health-care sector to confront the pandemic.7 The expedited and targeted training of a critical mass of health-care workers, followed by more broad-based workforce education, is of paramount importance to the success of ART programs in particular and to health-care sectors in general.8–10

The need to strengthen health-care worker capacity was identified by the Botswana Ministry of Health (MOH) and confirmed by a training needs assessment conducted in 2001. In response, Botswana embarked on the first phase of a national antiretroviral (ARV) training program.

PHASE 1: THE KITSO AIDS TRAINING PROGRAM

The KITSO AIDS Training Program, also known simply as KITSO, was created in 2001 by the MOH and the Botswana–Harvard School of Public Health AIDS Initiative Partnership for HIV Research and Education (BHP), with financial support from the African Comprehensive HIV/AIDS Partnerships (ACHAP), a collaboration between the government of Botswana, the Bill & Melinda Gates Foundation,
and the Merck Company Foundation / Merck & Co. Inc. KITSO is the Setswana word for “knowledge” and also serves as an acronym for “Knowledge, Innovation, and Training Shall Overcome” AIDS.

With the help of a private donation and the partnership of the MOH and BHP, the initial KITSO AIDS Training Program was developed in 2001 after a countrywide needs assessment. In 2002, Botswana announced the provision of free ART to all eligible citizens according to national treatment guidelines. Since Botswana did not have a medical school, the MOH partnered with BHP and ACHAP to devise and implement a standardized program to train Botswana’s health-care workers in HIV care and ART. Following the needs assessment and extensive stakeholder consultations, the KITSO AIDS Training Program was implemented by a newly formed national faculty who, with support from international advisers, designed country-specific training courses in HIV care and treatment.

In 2004, the MOH expanded KITSO’s didactic training by incorporating additional training partners in the country through a preceptorship program. Under the supervision and mentoring of a preceptor, newly trained health-care workers gained valuable hands-on experience in the practical application of their didactic training. In 2003, the training underwent further improvements with the development and implementation of the BHP–President’s Emergency Plan for AIDS Relief (PEPFAR) Master Trainer and Site Support Program (see section on Phase 2).

The KITSO training program has a number of distinguishing characteristics that have led to its success (see Box 1). According to the Botswana MOH, KITSO has been instrumental in Botswana’s national ART roll-out. KITSO training lectures have also been customized and used by ART training programs in several other countries, including Tanzania and Lesotho. KITSO lectures have also been translated for use in China.

### Program Design

The KITSO training modules serve as the national standard of training in HIV care and treatment throughout Botswana’s public and private health-care systems and are fully integrated with Botswana’s national HIV/AIDS treatment guidelines. The curriculum is also regularly updated by national and international experts to ensure that health-care professionals gain competency and confidence in the latest national standards of HIV care and treatment. Curriculum development and course implementation have been informed by the urgent need to train Botswana’s health-care workers in good clinical HIV care practice, without requiring long periods of staff release for training.

The MOH requirements to receive KITSO certification include full attendance at all sessions and completion of both a baseline assessment (pretest) and final examination (posttest) with a requisite passing grade. Health-care workers who meet the MOH requirements receive certificates of successful course completion. The KITSO-BHP team oversees training implementation, curriculum development, content updates, course examination, and certification.

### Box 1. Distinguishing Characteristics of the KITSO Training Program

- Botswana’s national training program directed by the MOH
- Country-specific curriculum, developed in Botswana for practitioners and patients in Botswana
- Standardized training modules that have been implemented by many training partners in a consistent fashion to train a high volume of health staff
- Responsiveness to the evolving training needs of Botswana’s health sector since its inception in 2001
An experienced and knowledgeable faculty provides instruction for KITSO-BHP courses. Faculty members are drawn from the KITSO team, BHP, ACHAP Clinical Preceptorship Program, the PEPFAR Master Trainer Program, and other development organizations. The course faculty includes national and international experts in the fields of HIV/AIDS prevention, treatment, care, education, and research.

Training for National ART Roll-Out

The first year of Botswana’s roll-out of ART to 31 treatment sites across the country was accomplished through a stepwise approach. The initial 31 sites included a main infectious disease care clinic (IDCC) that was integrated into the existing hospital (“mother site”) and linked to between two and five designated satellite clinics that conducted HIV screening and referrals. Treatment sites were first established in areas of high population density and easy accessibility, followed by the roll-out of ART to smaller and more rural sites. By March 2009 there were 31 hospital mother sites and 112 satellite ART sites.

The training of a critical mass of health-care workers at treatment sites was an essential step to the successful national roll-out of ART. Core treatment teams, which were prioritized for training, consisted of 20 staff members from the hospital IDCC and four staff members from each satellite clinic. The team was commonly comprised of 2 to 4 doctors, 10 to 12 nurses, 2 to 4 pharmacy staff, and 1 to 2 social workers. The approach that was used to deliver didactic training and clinical mentoring for each site is summarized in Box 2.

### Box 2. Steps in the Roll-Out of Training for Core Treatment Teams

**Step 1.** Core treatment teams received training in “AIDS Clinical Care Fundamentals” (ACCF) in either a facility-based or centralized format, depending on the size of the treatment site. Large treatment sites able to release sizable groups of health-care workers for training were offered facility-based training, while smaller treatment sites with limited staff were pooled with other facilities of similar size to receive centralized training over a period of four to six weeks (e.g., releasing 5 staff members per week over four weeks to train a total of 20 staff members). The training format for smaller facilities enabled simultaneous training of core treatment teams from multiple sites, while avoiding the interruption of health-care services that would have been caused by taking all health-care workers for training at one time. In Phase 2, the BHP-PEPFAR clinical master trainers also provided ACCF training to health-care workers at ART sites during site support visits.

**Step 2.** After the successful completion of ACCF training, one doctor, one nurse, and one pharmacy staff member from each treatment site were attached to one of two referral hospitals for the “Integrated Practical Attachment.” At the conclusion of the attachment training, participants returned to their treatment sites equipped to begin provision of ART and to provide basic mentorship to other health-care workers at that facility. PEPFAR clinical master trainers provided follow-up site and telephone support to all ART sites as part of Phase 2.

**Step 3.** As each treatment site’s opening date approached, the “Laboratory Fundamentals” module was conducted at the facility. With the support of PEPFAR laboratory master trainers, CD4 and viral load capacity testing was expanded to decentralized laboratories; master trainers also provided on-site and telephone support and mentoring. For support staff, the satellite module “Introduction to HIV & Biosafety” was implemented alongside the laboratory training, usually on consecutive days. (Note: All laboratory training now falls under the BHP-PEPFAR Laboratory Master Trainer program [see section on Phase 2].)

**Step 4.** Before the launch of each treatment site, an experienced ART practitioner (i.e., preceptor) from the ACHAP Clinical Preceptorship Program was assigned to the treatment site for three to six months to assist with final preparations and the ART launch, as well as to provide ongoing logistical assistance, clinical mentoring, and lectures. (Note: Currently, support for needs assessment, readiness assessment, preparation, launch, and mentoring is being performed by the BHP-PEPFAR clinical master trainers.)
Botswana’s health-care workers with the information and skills they need to begin providing basic ART and other HIV care services. Training is carried out using either a facility-based or centralized format, depending on the staffing needs of individual health-care facilities. This baseline module covers a total of 15 topic areas (see Box 3) and includes both adult and pediatric content. The module is comprised of lectures, case study discussions, practical exercises, and question-and-answer sessions, and concludes with a final examination. Following the initial training of core health-care worker teams for each treatment site, ACCF is now being provided

**KITSO-BHP Curriculum**

KITSO consists of didactic and practical core modules to facilitate ART roll-out, three advanced modules to consolidate and extend the HIV/AIDS knowledge and experience of Botswana’s health-care workers, and two satellite modules for non-medical staff (see Figure 1).

*Didactic Core Modules*

AIDS Clinical Care Fundamentals (ACCF), a four-day didactic training course for doctors, pharmacists, nurses, pharmacy technicians, and social workers, has served since 2001 as a gateway course to provide Botswana’s health-care workers with the information and skills they need to begin providing basic ART and other HIV care services. Training is carried out using either a facility-based or centralized format, depending on the staffing needs of individual health-care facilities. This baseline module covers a total of 15 topic areas (see Box 3) and includes both adult and pediatric content. The module is comprised of lectures, case study discussions, practical exercises, and question-and-answer sessions, and concludes with a final examination. Following the initial training of core health-care worker teams for each treatment site, ACCF is now being provided

to all health-care workers in Botswana. Staff reassignment, resignation, and replacement create a continuing need for the baseline training provided by the ACCF module. Between July 2001 and December 2008, 6,304 participants completed this module. During that period, 66% of trainees were from the nursing professions and 16.4% were medical doctors (Figure 2).

“AIDS Clinical Care Fundamentals Refresher/Update,” a two-day refresher course first implemented in January 2008, was developed in response to the high demand for refresher training. It also serves to update previously trained health-care staff on the most recent changes to the national treatment guidelines. Incorporating information from the new guidelines along with care and treatment fundamentals, the training covers HIV testing, ART eligibility, principles of ART, management of toxicities, management of treatment failure, prevention of mother-to-child transmission (PMTCT), and treatment of TB and other opportunistic infections.

“Integrated Practical Attachment,” designed as a hands-on follow-up to ACCF, utilized the high-volume ART clinics established at Botswana’s two referral hospitals for clinical mentoring in adult and pediatric ART. (Note: This module was subsequently replaced by the BHP-PEPFAR Clinical Master Trainer program in 2004 [see section on Phase 2].) Doctors, nurses, and pharmacy staff were taught under the guidance of experienced national clinicians, who in turn were supported by international experts from various MOH collaborators. Doctors were attached for four weeks of mentorship, during which time they maintained a clinical logbook and developed the confidence and skills to treat patients independently while receiving expert supervision and support. Nurses and pharmacy staff were attached to the same ART clinics for two-week rotations to gain experience in the national protocols for adherence counseling, treatment initiation, and treatment follow-up.

“Laboratory Fundamentals,” a one-day didactic and practical module, was designed for laboratory personnel and health-care workers involved in the collection and processing of laboratory specimens for the ART program. This training included practical background on the testing protocols for the ART program, sample collection, labeling, testing procedures, results interpretation and reporting, and basic biosafety. (Note: The “Laboratory Fundamentals” module was replaced by the

training in ART and advanced treatment challenges, as well as in-depth information in the areas of HIV virology and immunology. The course familiarizes participants with the full range of ARV drugs and provides strategies for the management of treatment failure, interpretation of drug resistance, assays, design of “salvage” regimens, and the understanding of short- and long-term ARV side effects and toxicities. Extensive case study discussions incorporate actual patient cases provided by course participants to illustrate and reinforce optimal care and treatment strategies.

Advanced Modules
Following the national roll-out of ART, KITSO introduced two new courses, “Advanced HIV/AIDS Care and Treatment” and “Medication Adherence Counseling,” to build on ART providers’ prior training and hands-on experience. Both courses were designed to provide responsibility-specific continuing and advanced training support for health-care workers from ART sites. These highly interactive courses, conducted in a centralized format, build specialized knowledge and skills integral to the long-term success of Botswana’s ART program.

“Advanced HIV/AIDS Care and Treatment” is an intensive five-day course for doctors and pharmacists who have successfully completed ACCF and have subsequently gained clinical experience in ART. The course combines lectures and interactive case discussions to provide comprehensive training in ART and advanced treatment challenges, as well as in-depth information in the areas of HIV virology and immunology. The course familiarizes participants with the full range of ARV drugs and provides strategies for the management of treatment failure, interpretation of drug resistance, assays, design of “salvage” regimens, and the understanding of short- and long-term ARV side effects and toxicities. Extensive case study discussions incorporate actual patient cases provided by course participants to illustrate and reinforce optimal care and treatment strategies.

The course covers adult, adolescent, and pediatric HIV care, with input from the Botswana-Baylor Children’s Clinical Center of Excellence and the pediatric departments of the two referral hospitals in Botswana: Princess Marina Hospital and Nyangabgwe Hospital. Special emphasis is placed on primary care for children living with HIV and on disclosure issues, especially for children and adolescents. Each advanced course features an evening

Responsive and Flexible Implementation

The KITSo model of training has mirrored the MOH’s general approach to national ART roll-out. Training was initially a centralized, vertical effort to equip core treatment teams to participate in the ART roll-out. KITSo courses are now offered in centralized, regional, and facility-based formats by KITSo faculty, BHP master trainers, and other training partners.

Since July 2001, KITSo-BHP has adapted its curriculum in response to the evolving training needs of health professionals in Botswana. Responsiveness and flexibility have enabled KITSo-BHP to problem solve and respond in a targeted fashion to the training goals as defined by the MOH and program stakeholders.

Teaching Tools

To augment the didactic courses offered by KITSo, the program has developed a number of valuable teaching tools, including CD-ROMs, a video lecture series, pill charts and pediatric dosing charts, and PMTCT flow charts. In 2002 a video-cassette series, bound course readings, and case studies were developed for use as training tools. Five CD-ROMs have been developed: Course for Physicians: Antiretroviral Therapy (2001), Lessons from Botswana: A Comprehensive Instructional Guide on HIV and AIDS Medicine for Health Professionals (2002), HIV and AIDS Care and ARV Therapy (2003), AIDS Clinical Care Fundamentals (2006), and AIDS Clinical Care Fundamentals (with the 2008 national ARV guidelines). These teaching tools provide narrated PowerPoint lecture slides.

Distance Education

Since January 2007, KITSo-BHP has formally established distance education through CD-ROMs as a means of providing the ACCF course to relevant health-care workers. After reviewing the CD-ROM and course materials, health-care workers come to
Gaborone for one day to participate in case discussions and take the final examination. The criteria for certifications are the same as for those taking the full in-class training.

**KITSO AIDS Training Program Achievements**

Nurses and doctors receiving ACCF training take different final examinations tailored to their clinical responsibilities. In an analysis of exam scores for the period 2003–2006, both professions demonstrated marked improvement in knowledge, as illustrated by the improved scores between the baseline assessments and final examinations. The mean change in pre- and post-test score was significantly higher for nurses ($P<.001$) than for doctors, most likely due to lower baseline knowledge among nurses and the fact that doctors regularly achieved the maximum scores (ceiling effect) at the time of final examination.

As part of site preparation, 553 health care workers were trained in “Laboratory Fundamentals,” and 687 support staff participated in “Introduction to HIV & Biosafety.” In addition, 95 health-care workers completed “Integrated Practical Attachment” during the initial roll-out period.

The advanced modules, “Medication Adherence Counseling” and “Advanced HIV/AIDS Care and Treatment,” more recent additions to the KITSO curriculum, have been conducted for 683 and 470 health-care workers, respectively. Through December 2008, 1,457 nonmedical professionals had completed the satellite module “Introduction to AIDS Clinical Care.” During this same period, 733 physicians and pharmacists were trained in the “AIDS Clinical Care Fundamentals Refresher/Update.”

**Program Assessment and Review**

Over the past eight years of the program, KITSO-BHP’s curriculum development and implementation have been enhanced by reviews conducted by the MOH, stakeholders, faculty, participants, and external evaluators. As KITSO-BHP’s funder, ACHAP has twice sponsored external evaluations that included the KITSO-BHP training efforts. In May 2003, Health and Development Africa, a South Africa–based consultancy, conducted an evaluation and subsequently released a report entitled *Evaluation of the KITSO AIDS Training Program and Clinical Preceptorship Program*. In 2004, John Snow International (UK) conducted a review of KITSO-BHP as part of its midterm evaluation of ACHAP-supported programs.

In 2006, KITSO-BHP and the MOH jointly conducted a long-term program evaluation to assess the impact and reach of KITSO training. Site leaders from 17 ART sites were interviewed and 494 former training participants completed survey questionnaires and knowledge assessments. The final evaluation report was released by the MOH in January 2008, the key findings of which are summarized in Box 4.

**PHASE 2: THE BHP-PEPFAR MASTER TRAINER AND SITE SUPPORT PROGRAM**

As the number of ART sites and enrolled patients increased throughout the country, it became evident that an expanded master trainer and site support system was needed. In response to the MOH’s demonstrated need for additional capacity building, Harvard School of Public Health, in conjunction with the MOH and BHP, initiated the BHP-PEPFAR Master Trainer and Site Support Program in March 2003 as the second phase of country-specific training and capacity-building activities.

BHP-PEPFAR is a multipronged project aimed at developing sustainable training capacity in the clinical care and treatment of people living with HIV, expanding decentralized CD4 and viral load laboratory testing, and strengthening the MOH’s monitoring and evaluation capacity to monitor the
Clinical Master Trainer Program

The Clinical Master Trainer (CMT) program provides site-specific, ongoing training and mentoring, and on-site and telephone support to designated MOH ART sites. These activities help ensure that health-care professionals stay current on all aspects of HIV treatment and care, that they are strengthening and reinforcing their skills on a continual basis, and that they are receiving sufficient technical support. The MOH devised the original framework for the project based on the belief that the best way to achieve these goals was to create sustainable training capacity at the sites themselves through the identification and training of site-level master trainers, including a physician, nurse, and pharmacist, at each ART site. BHP-PEPFAR has established a clinical master trainer corps, currently consisting of six physicians (including two pediatricians), two pharmacists, and four nurse-midwives, all of whom are highly experienced in HIV treatment and care for both adults and children. These core master trainers—some of the most experienced HIV/AIDS practitioners in the country—train and provide ongoing site and telephone support to the site-level master trainers. The approach used is based on a modified, country-specific version of the World Health Organization (WHO) Integrated Management of Adult and Adolescent Illness (IMAI) guidelines. Building on the KITSO didactic training, the program has become an important catalyst in the government’s effort to create a comprehensive, integrated, and decentralized HIV/AIDS treatment program from what had been a more traditional series of vertical programs addressing specific aspects of HIV/AIDS care (e.g., ARV, PMTCT, TB treatment and prevention, sexually transmitted infections, etc.). The components crucial to the program’s successful implementation are summarized in Box 5.

Laboratory Master Trainer Program

The Laboratory Master Trainer (LMT) program was developed to support the government’s goal of establishing decentralized laboratories capable of performing CD4 and viral load testing. This was done in order to relieve the burden and time delays at the country’s two national HIV reference laboratories in Gaborone and Francistown. Currently, the government of Botswana, along with ACHAP and the Centers for Disease Control and Prevention—Government of Botswana Partnership (BOTUSA), is constructing or expanding and equipping the new laboratories.

- 90% of KITSO-trained physicians were actively prescribing ART.
- 85% of respondents reported that they were working in a capacity that allowed them to use the skills and information taught by KITSO.
- 89% of respondents stated that they had provided instruction to their colleagues: 64% had provided theoretical instruction, while 48% had provided practical instruction to untrained co-workers.
- Facility leadership across the sample sites reported that KITSO training had improved patient care, particularly the management of opportunistic infections, adherence counseling, and the management of ARV drugs and side effects.
- Results of the knowledge retention test were below expectations. This is believed to be a result of the limitations of didactic courses and highlights the need for continuing education opportunities, performance feedback, and mentoring beyond the six KITSO courses evaluated.

The efficacy of the national ART program (“Masa”). The PEPFAR-funded project consists of three program components, which are detailed in the following sections.
Under BHP-PEPFAR’s national laboratory director, six core laboratory master trainers provide training in conducting CD4 and viral load tests, using a similar master trainer/site support approach as the CMT program. The MOH has recently asked the LMT program to add training in hematology and chemistry, as well as training on rapid HIV testing of adults and dried-blood-spot testing of infants. Program activities include site needs assessments for each decentralized laboratory, centralized attachment training at the Botswana-Harvard HIV Reference Laboratory (BHHRL) in Gaborone for site laboratory master trainers, on-site support to the new trainees in launching these tests at the decentralized laboratories, follow-up support and evaluation visits to each laboratory, and telephone support through a toll-free line.

**BHP-PEPFAR Program Achievements**

To date, the clinical master trainers have provided on-site support and training in care and treatment at all 31 hospital mother sites and their associated 112 satellite clinics (in addition to ongoing support at the IDCC/Princess Marina Hospital). Seventy clinics have been upgraded to ART sites and are being fully supported and mentored. During support at IDCC and other ART sites in the past five years, 17,654 patients were directly attended by physician master trainers and 7,548 patients were attended by nurse master trainers.

**Task Shifting**

In 2007, task shifting was implemented to mitigate the critical shortage of pharmacists, pharmacy technicians, and doctors/prescribers for the ART roll-out in Botswana. By adding pharmacists to the clinical master trainer corps, clinical and pharmacist master trainers have taken a lead role in training nurses in ARV prescribing and dispensing. These trainers provide comprehensive training and site support during the critical stages of ART roll-out and the upgrading of ART sites to become prescribing and dispensing sites. To date, a total of 63 nurses have attended the monthlong prescribing and dispensing course and 127 have attended the four-day dispensing course.

**Management of Treatment Failure**

Due to the success of the national ART roll-out and the continuous upgrading of clinics to full
prescribing and dispensing capacity, sites need to be vigilant in the areas of treatment failure and management. In partnership with the Masa program, all sites supported by clinical master trainers have been set up with treatment failure registries. The National Monitoring and Evaluation Committee, formed in 2007, is currently drafting the national protocol on early warning indicators.

**Telephone Site Support**

The telephone site support program allows clinic staff to receive real-time support from the master trainers. Both clinical master trainers and laboratory master trainers track all calls, which concern issues such as ART complications and necessary changes in drug regimens; pediatric HIV management; and reagent, equipment, and logistical laboratory issues. Site calls to the Monitoring, Evaluation, and Quality Improvement (ME&QI) Unit staff at the MOH deal mostly with reporting uniformity and deadlines, meeting and workshop notification, and new pharmacy data collection. More than 3,300 calls were fielded by representatives of the three BHP-PEPFAR components (i.e., CMT, LMT, and M&E) in the last year.

**Laboratory Decentralization**

Efforts by the laboratory master trainers to decentralize laboratory services have resulted in 23 sites now performing CD4 counts and 10 sites now performing viral load testing. Infant HIV diagnosis (DNA polymerase chain reaction [PCR]), which had previously been performed only at the BHHRL, was initiated at Jubilee HIV Reference Laboratory during 2008. More than half of the CD4 tests performed nationally are done at decentralized laboratories; this has significantly decreased the turnaround time of results, demonstrating the success of the decentralization process. During 2008, 160,877 CD4 and 30,650 viral load tests were performed in decentralized laboratories.

**ME&QI**

Clinical master trainers emphasize quality assurance and improvement initiatives in their site training. A quality improvement sensitization workshop for district and site leadership was held in June 2008 with 45 attendees. In addition, district health teams, Ministry of Local Government staff, and ART site managers participated in the Harvard-PEPFAR Tri-Country Conference, which focused on the quality management and improvement of HIV care and treatment programs.

Since January 2008, QI of HIV/AIDS services has been part of the mandate of the M&E Unit, now referred to as the ME&QI Unit. The ME&QI Unit continues to expand its role not only to cover ME&QI activities within the Masa program, but to have a greater role in integrating programs within the MOH Department of HIV/AIDS Prevention and Care (DHAPC). BOASA II, a new electronic application developed by the ME&QI Unit, links to the existing stand-alone Masa databases and produces standardized monthly clinical and pharmacy reports. The BOASA application was implemented in all Masa site hospitals in March 2008. To date, more than 45 million records have been extracted. The software development team of the ME&QI Unit continues to provide both site and telephone support. BHP-PEPFAR also supports 10 data entry clerks (DECs) who have been posted throughout the country. The DECs are in the process of updating data and improving data quality at ART sites. Early warning indicators have been identified and data collection mechanisms finalized.

**SUMMARY**

Training is a necessary prerequisite for the scale-up of HIV care and treatment programs. In Botswana, there has been an increase in both the number of health-care workers completing the ACCF course and the number of patients receiving ART. With over 112,000 people currently receiving ART in the
BEGINNING IN JULY 2005, BHP-PEPFAR began supporting the government of Botswana in establishing a Monitoring, Evaluation, and Quality Improvement (ME&QI) Unit within the national ART program (“Masa”). In July 2007, at the request of the Department of HIV/AIDS Prevention and Care (DHAPC) director, the unit expanded its role to become the official M&E unit of the DHAPC. The resultant ME&QI Unit, headed by an M&E specialist, is comprised of two data managers, a data manager understudy, a data quality officer, and 10 data entry clerks deployed to ART sites.

The ME&QI Unit is developing a uniform manual and computerized ART patient tracking system that will provide data on indicators for the national ART program. This process involved the development of standardized indicators, reporting instruments, and a uniform reporting schedule. The unit upgraded the BOASA electronic reporting application to include production of the pharmacy reports. This upgrade was deployed to 28 ART sites that have started producing standard pharmacy reports. The ME&QI Unit also tracks private sector patients, including those “outsourced” from the public to the private sector through the newly established public-private partnership (PPP) program. The unit is now working on linking data from ARV pharmacies, laboratories, the TB program, and other HIV/AIDS programs. To facilitate this process, a data warehouse server was purchased and is currently located within the MOH. While the system initially focused on the ART program, plans for eventual expansion to other HIV/AIDS programs will create a comprehensive M&E system serving the needs of the newly created MOH DHACP.

The DHAPC is working with the ME&QI Unit to identify indicators and develop standardized instruments and reporting mechanisms as well as an overall M&E plan for the DHAPC. The ME&QI Unit will also set up a national QI team and coordinate QI efforts in the MOH programs, as well as those of other stakeholders.

Beginning in July 2005, BHP-PEPFAR began supporting the government of Botswana in establishing a Monitoring, Evaluation, and Quality Improvement (ME&QI) Unit within the national ART program (“Masa”). In July 2007, at the request of the Department of HIV/AIDS Prevention and Care (DHAPC) director, the unit expanded its role to become the official M&E unit of the DHAPC. The resultant ME&QI Unit, headed by an M&E specialist, is comprised of two data managers, a data manager understudy, a data quality officer, and 10 data entry clerks deployed to ART sites.

The ME&QI Unit is developing a uniform manual and computerized ART patient tracking system that will provide data on indicators for the national ART program. This process involved the development of standardized indicators, reporting instruments, and a uniform reporting schedule. The unit upgraded the BOASA electronic reporting application to include production of the pharmacy reports. This upgrade was deployed to 28 ART sites that have started producing standard pharmacy reports. The ME&QI Unit also tracks private sector patients, including those “outsourced” from the public to the private sector through the newly established public-private partnership (PPP) program. The unit is now working on linking data from ARV pharmacies, laboratories, the TB program, and other HIV/AIDS programs. To facilitate this process, a data warehouse server was purchased and is currently located within the MOH. While the system initially focused on the ART program, plans for eventual expansion to other HIV/AIDS programs will create a comprehensive M&E system serving the needs of the newly created MOH DHACP.

The DHAPC is working with the ME&QI Unit to identify indicators and develop standardized instruments and reporting mechanisms as well as an overall M&E plan for the DHAPC. The ME&QI Unit will also set up a national QI team and coordinate QI efforts in the MOH programs, as well as those of other stakeholders.
of the MOH to build health-care worker capacity and assure the quality of HIV care and treatment in Botswana.

Flexibility in the implementation of training has made it possible to train a high volume of staff without disruption of overall health-care services. Training staff from large urban and semi-urban health-care centers, as well as from small rural facilities, requires different logistical approaches in training implementation. Other ART initiatives in the region will need to develop their own strategies according to their individual needs and resources.\textsuperscript{3,6,9,10,16} Operations research on optimal training methodologies, the effectiveness of various follow-up mechanisms, and long-term patient outcomes is warranted.\textsuperscript{9}

Another important feature in the design and implementation of KITSO has been the close collaboration of national faculty with international HIV experts. This ongoing process began in 2001 and resulted in the creation of training modules that present up-to-date medical and scientific information within the context of existing national guidelines and available diagnostic capacities. This mutual exchange of expertise has built capacity in all aspects of ART and has helped clinicians in Botswana to develop their own experience and expertise. When the national ART program was officially launched in January 2002, a core of capable clinicians was already in place. Training continued ahead of the roll-out timetable, preparing sites in sequence for their involvement in the national program.

Efforts to scale up ART programs in sub-Saharan Africa have been constrained by a lack of trained medical personnel, stemming from both acute staff shortages and general inexperience and lack of training in ART. Recruitment of additional health-care workers is often a slow process and in many cases is not an option. Innovative task shifting, which can increase available health-care capacity among existing staff, can help to rapidly address unmet patient care needs; however, this approach necessitates an even greater emphasis on standardized and expanded training efforts.\textsuperscript{3,6,9,10,16}

**ONGOING CHALLENGES**

With ART now available throughout the country, Botswana is well positioned to further increase access to ART by extending ARV prescribing and delivery of comprehensive ART services to existing, affiliated satellite clinics, even if physicians are not available in these clinics. Some satellite clinics have already begun to provide ART, and training of all staff in these facilities is currently under way. There is an ongoing need at these sites for continuing education, refresher courses, advanced training, and timely information regarding revisions and amendments made to national treatment protocols.

The long-term need for ART in Botswana and elsewhere requires that adequate knowledge of HIV care and treatment be integrated into the pre-service training curricula for all health professionals. The retention of trained staff with ART experience is critical to the program’s long-term success. KITSO-trained health-care workers have been recruited into HIV/AIDS programs in other countries, a fact that underscores the successes of Botswana’s training and treatment efforts. However, this recruitment hampers the expansion of the Botswana program, especially in the context of a generally understaffed health system. In addition, care should be taken to avoid transferring staff with ART experience to locations and duties that do not utilize their specialized knowledge and skills.

Finally, training programs such as KITSO and BHP-PEPFAR cannot remain static. In order to be successful, training programs must reflect the continual advances in HIV care as well as the evolving needs of the health sector they serve.
KITSO and BHP-PEPFAR seek to be flexible and responsive as new research emerges and as Botswana’s training needs change. For example, in view of the fact that a majority of patients in the ART program are women, and in view of many women’s renewed desire to have a child following restoration of health on ART, a new module on HIV and women’s health is now being developed to focus on special care and treatment considerations for women living with HIV, including family planning issues.

CONCLUSION
As a standardized, national training program coordinated by the MOH, the KITSO AIDS Training Program and the BHP-PEPFAR Master Trainer and Site Support Program collaboration is a model of HIV/AIDS care training for rapidly expanding the capacity of a national health system to respond to the HIV pandemic. KITSO and BHP-PEPFAR have been indispensable elements in Botswana’s national roll-out of ART. Through timely implementation of a standardized curriculum, broad collaboration, high-quality and country-specific instruction, effective monitoring and evaluation, and strong MOH leadership and coordination, the KITSO/BHP-PEPFAR approach could serve as a training model for many countries in the early stages of national HIV care and ART program implementation.

ACKNOWLEDGMENTS
Portions of this chapter were adapted from a previously published article: Bussmann C, Rotz P, Ndwapi N, et al. Strengthening healthcare capacity through a responsive, country-specific, training standard: the KITSO AIDS Training Program’s support of Botswana’s national antiretroviral therapy rollout. Open AIDS J. 2008;2:10-16.

The authors would like to acknowledge the leadership and guidance of the Botswana Ministry of Health and the Botswana–Harvard School of Public Health AIDS Initiative Partnership for HIV Research and Education (BHP), the commitment and dedication of KITSO faculty members and the KITSO-BHP team, and the contributions of all training partners participating in the broader KITSO AIDS Training Program, particularly the BHP-PEPFAR Master Trainer and Site Support Program, the Botswana-Baylor Children’s Clinical Center of Excellence, the University of Pennsylvania, the ACHAP Clinical Preceptorship Program, and the Private Practitioner Association of Botswana.

KITSO-BHP has been made possible through support from ACHAP and the Botswana Ministry of Health. BHP-PEPFAR has been made possible through support from the Health Resources and Services Administration / HIV/AIDS Bureau (HRSA/HAB), as part of its international AIDS activities as an implementing organization for PEPFAR.

Development and Implementation of Training Packages for PMTCT and Pediatric HIV Care

Linda S. Podhurst, Mary Jo Hoyt, Farai Dube, Nomfundo Nhlapo, Lucy Connell, and Robert Ayisi

COMPREHENSIVE PROGRAMS FOR THE prevention of mother-to-child transmission of HIV (PMTCT) in conjunction with effective linkages to pediatric HIV care and treatment can reduce significantly the number of children who become infected with HIV while improving outcomes for those already infected. To facilitate the provision of these critical services, it is essential to expand the pool of health-care workers trained in PMTCT and pediatric care. Such training activities, which can take a number of forms, are important for the success of the widespread scale-up of PMTCT and pediatric HIV care now under way. The severe shortage of skilled health-care workers in many developing countries remains a major barrier to the development and expansion of lifesaving children’s health services.

Frontline health-care providers in a position to provide PMTCT and pediatric HIV care services are often already overburdened by heavy patient caseloads and severe staff shortages. Ideally, PMTCT services can be offered in all settings that provide reproductive health care, including those that utilize traditional birth attendants. Pediatric HIV care serves a much smaller population than PMTCT and can be provided by relatively fewer clinicians. However, training for pediatric services lags significantly behind training for PMTCT and adult HIV care and treatment programs. The provision of pediatric HIV care requires specialized training, as well as a shift in traditional models of service provision, so that chronic care can become the norm rather than the exception. Until very recently, most pediatric health care in resource-limited settings has focused on well-child and acute care, with limited services for the care of children with chronic illnesses.

This chapter discusses strategies and experiences in developing training materials and approaches for the implementation of training programs for PMTCT and pediatric HIV care. Training is an important tool for addressing the technical and emotional demands placed on health-care workers when HIV prevention and treatment services are added to their existing workloads. Training programs give health-care workers opportunities to acquire knowledge and skills while teaching them how to take on new roles and cope with the emotional demands of HIV care. The following section highlights how the planning of training programs and related materials development can address the needs of the target population and the specific
services to be delivered. Later in the chapter, case studies provide examples of successful training initiatives.

**DEVELOPMENT OF TRAINING MATERIALS**

The processes used to develop training materials vary greatly depending on program characteristics (see Table 1). The process for materials development should reflect the scale and scope of the training needs. Centralized, national leadership may be especially important during the development of large-scale training efforts, such as training to support nationwide scale-up of comprehensive PMTCT services, whereas regional or local leadership is sufficient for the development of training programs for smaller or more localized initiatives. This section describes three model processes for training materials development that strike varying balances between national and international participation. The descriptions are meant to serve as useful reference points for understanding the variety of processes that can be used. Naturally, variations of these models involving different mixes of national and international cooperation are also possible.

**Materials Developed by National or Regional Experts**

A rapid method for responding to the need for training materials is development by a small, dedicated group of national or regional experts in a specific area of expertise (e.g., perinatal HIV transmission or pediatrics). These experts may come together in a number of ways, such as clinicians and/or educators working to address the needs arising in clinical settings. Experts convened regionally or nationally by the government to work with the country’s ministry of health are often referred to as a technical working group (TWG). There are significant strengths that emerge from this approach to training materials development:

- Practitioners are invested in the materials, and their investment often generates buy-in for the recommended procedures to facilitate service delivery.
- Content is likely to reflect country-specific cultural norms, values, and priorities.
- Materials development is a capacity-building activity that encourages developers to
  - focus on the clarity of the protocols for service delivery;
  - identify and address gaps;
  - integrate national policies for consistency with training;
  - identify and develop policies that have not yet been addressed (e.g., confidentiality within the national strategy for HIV/AIDS and its application to PMTCT, or disclosure policies for pediatrics); and
  - change clinical practice to increase coordination of PMTCT and pediatric care.
- Involvement of a TWG is likely to focus on the population-specific considerations of targeted patient groups (i.e., pregnant women, their partners and families, as well as HIV-exposed and -infected children), with training content tailored to patient and health worker needs.

However, there are some potential drawbacks to the development of materials exclusively by national or regional experts without input from international partners or resources:

- The balance and quality of the materials may be skewed due to the varying availability and inclusion of experts (e.g., nutrition experts may place substantial emphasis on details of infant feeding rather than on less familiar content about antiretroviral prophylaxis or counseling and testing).
- Focus of materials may be less multidisciplinary than materials developed with international input (e.g., materials development may be dominated by physicians, because contributions

from nurses or other allied professionals may be undervalued or seen as inferior, rather than valued for their unique content and perspective).

- There may be limited access to the most up-to-date resources and to experienced PMTCT or HIV clinicians or educators. Reference books may be the only resources available in a particular setting; these texts may not reflect the latest internationally recognized guidelines or training methodologies.

**Materials Developed Collaboratively by National and International Experts—Harmonization**

Midway on the continuum of materials development processes is the harmonization model. In this model, national experts (e.g., the TWG) collaborate with a select group of international experts to develop training materials. This model has the potential to build on the strengths of the national expertise and materials and address some of the potential drawbacks of an exclusively national development process. The collaborative nature of this process is a significant advantage of the model, which may result in some or all of the following positive outcomes:

- International standards and evidence-based data are introduced by international partners; such standards and data are reviewed and incorporated when appropriate for the setting, as guided by national partners.
- There is access to a broader range of expertise that includes experience in various training methodologies.
- Knowledge and experience shared in the act of collaboration builds capacity among both international and national experts.
- Exchange of perspectives reduces the potential for a biased emphasis on certain areas.
- Appropriate consideration can be given to the impact of infrastructure, resources, and culture.
- Process of integrating materials results in enhanced buy-in from national experts.
- Collaboration may encourage a multidisciplinary approach.

At the same time, the following challenges may arise from the harmonization process:

- The need to negotiate content and perspectives is time consuming.
- Negotiations may be intensified by cultural variability between partners.
- Value differences may present barriers (e.g., the question of whether an HIV-positive woman should have a baby).
- Unequal partnerships may result in the inclusion of content that is not acceptable in the national context, and implementation may be compromised by lack of buy-in.
- Access to international collaboration may be limited due to cost and logistics.

The development of comprehensive, evidence-based training materials to prepare health-care workers to implement PMTCT and pediatric HIV care and treatment programs presents an enormous human capacity and fiscal challenge for resource-limited settings. The availability of internationally developed training materials that can be adapted to address national needs and integrated with existing materials provides a useful starting point for the collaborative materials development process. Generic training packages can be extremely helpful in this context. The U.S. Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have lent considerable support for the development of training materials that meet international standards. They have done this through the development of the PMTCT Generic Training Package (PMTCT GTP), the

---

Integrated Management of Childhood Illness (IMCI), the Integrated Management of Adolescent and Adult Illness (IMAI), and the Complementary Course on HIV/AIDS. These training packages target frontline health-care providers in resource-limited settings and serve as a training template that national experts can rapidly adapt to meet local needs. Where training materials already exist, the GTP, IMCI, IMAI, and other materials can be used to quickly strengthen and update the contents of national materials. The Kenya harmonization case study (presented later in this chapter) provides a comprehensive example of how the PMTCT GTP was used in the development of a national training curriculum. The International Maternal Pediatric and Adolescent AIDS Clinical Trials (IMPAACT) network Global Training Program case study (presented later in this chapter) provides an example of a collaborative partnership to address gaps and enhance existing national training programs for PMTCT and pediatric HIV care.

Materials Developed by an International Partner

At the other end of the continuum is a model in which materials are developed by an international partner and then implemented nationally and regionally. WHO has developed a number of such products that provide guidance on the gold standard for disease management worldwide. They include the Clinical Care Essentials, seven essential manuals on clinical care that provide key knowledge to health-care professionals, and HIV and Infant Feeding Counselling: A Training Course. Unlike the PMTCT GTP, however, these materials do not include specific guidance about where and how to insert local policies and guidelines; nor do they provide guidance for areas in which national practices need to be considered and addressed. For resource-limited settings, this model of materials development, which features the significant involvement of one or more international partners, offers the advantage of minimal fiscal and time investment at the national level. Key strengths of this model include the following:

- Materials are widely used in a range of international settings, have often been pilot-tested, and have some proven efficacy.
- The product benefits from a broad range of multidisciplinary expertise.
- Widespread availability of content expertise allows for more comprehensive coverage of issues using evidence-based data.
- Training expertise may facilitate use of a broader range of educational methodologies.
- Additional human resources provided by international partners facilitate more rapid completion of materials.
- External funding may depend on meeting international standards, and these materials provide the information needed to meet those standards.
- The materials preparation process allows clinicians to benefit from external sources of information or support.
- Exposure to and influence of international norms fosters increased awareness of human rights issues that have an impact on affected groups.

The strengths may be compromised by challenges that result from the absence of national expertise, such as the following:

- Standards and protocols may not be relevant to or realistic for the setting.

\*Available at http://www.who.int/bookorders/WH/destart.jsp?sessionid=1&colidan=1&colcol=93&codch=204.
\*Available at http://data.unaids.org/Publications/External-Documents/who_fch_cah_00-3_en.pdf.
• Policy and service delivery priorities may not be adequately understood and appropriately addressed.
• Resource constraint considerations and cultural values may not be sufficiently considered.
• Content may not reflect the local health-care infrastructure.
• Country-expert consultation networks may not be incorporated into materials.
• The capacity-building benefit from national TWG involvement is lost.
• Clinicians and trainers may not be interested in a product that they have not played a role in developing.

PMTCT AND PEDIATRIC HIV CARE TRAINING

Conducting a Needs Assessment for PMTCT and Pediatric HIV Care Training
The materials development process begins with a needs assessment to learn about the training needs of the target audience as well as to catalogue existing content to ensure that the training program responds effectively to a given set of regional or national requirements. The mechanism used to conduct the needs assessment varies; in general, rapid strategies are used to meet the urgent need for training. For PMTCT programs, the assessment will look at the training needs associated with the scale-up of PMTCT services and will guide the development of sustainable, large-scale national training programs and a national training plan. For pediatric HIV care programs, the assessment will examine the ways in which the number of trained health workers with the capacity to provide pediatric HIV care can be expanded, as well as methods that can be used to clinically mentor and support the development of expertise among other health workers. Rapid assessment strategies include these:

• Direct observation of site(s) using a detailed checklist to gather information about staffing, space, reference materials, equipment, laboratory, pharmacy capacity, and so on
• Open-ended interviews with frontline providers and key stakeholders (see “Developing a Training Plan” for key questions to discuss)
• Desk review of related policies, guidelines, strategic planning documents, and training materials

From the time the needs assessment is initiated until dissemination and roll-out of the final training materials, it is of the utmost importance to engage with and elicit feedback from a broad range of stakeholders. Whoever ultimately makes decisions on training policies and the content of training materials will benefit enormously from the opportunity to discuss the training development process with the many partners committed to quality PMTCT and pediatric service delivery. The success of training materials is measured by their utilization by various partners. Seeking, respecting, and incorporating the input of partners in-country is the key to broad acceptance of training materials that provide a consistent “take-away” message for the delivery of services to pregnant women and families affected by HIV. Ultimately, the success of training programs is indicated by the scale-up of PMTCT services staffed by trained health-care workers with quality assurance reviews of clinical practice indicating that clients and families are receiving targeted services according to established policies and procedures (e.g., voluntary counseling and testing, antiretroviral prophylaxis and treatment, infant feeding counseling, etc.).

Developing a Training Plan
The training plan takes into account the training infrastructure, available resources, time frame, and monitoring and evaluation plan. The responsible partners and timeline for each part of the plan are
Development of Training Content

The materials developed need to be evidence-based and provide a comprehensive, accurate description of national policies, procedures, and protocols. When it is expected that training will be utilized on a long-term basis, an expert advisory group, such as the TWG or a separate panel of experts, monitors developments in PMTCT and pediatric care to ensure that materials are updated as needed; existing policies, procedures, and protocols are changed; and new policies are developed as required. A comprehensive package of training materials will include manuals and tools for the trainer and participants during the training course as well as clinician support tools (i.e., job aids) that can support the application of newly acquired skills in the clinical setting.

The trainer manual for a direct training or a training-of-trainers course should be comprehensive enough to allow an experienced trainer to confidently conduct the training after reviewing the manual contents. The objectives for each session must be stated clearly. Consistent, quality training can be facilitated by slides that include trainer notes, interactive activities that include trainer instructions and support materials, role-plays that are fully described and/or scripted, and ready-to-use evaluation materials.

The provision of high-quality pediatric HIV care services requires a considerable number of specific and diverse skills, from intensive counseling and patient education to management of pediatric phlebotomy. Because of the unique aspects of pediatric HIV care, adult HIV care experience alone is not sufficient preparation for addressing the specific needs of infants and children. Training involving the transfer of information without a practical component is also inadequate in settings where health-care services are primarily delivered by nurses or other midlevel providers. Such providers need more...
comprehensive training since they generally have little to no experience in pediatric HIV management and limited access to on-site supervision by experienced clinicians. While training programs for PMTCT may adequately prepare participants for clinical practice by providing opportunities to apply their skills in the training setting, opportunities to practice in the work setting under the supervision of a mentor are highly desirable. If mentoring is performed as part of the training, materials that offer guidelines for mentoring and learning goals for trainees are helpful tools for increasing the likelihood that participants will further develop and apply their newly acquired knowledge and skills in the work setting. The case study of the Enhancing Children’s HIV Outcomes (ECHO) project in South Africa (later in this chapter) offers an illustrative example of a successful mentoring program.

Implementation of Training
It is often challenging to identify experienced and highly skilled trainers who are also experts in the required content areas. In addition to content expertise and clinical experience, training skills are an important selection criterion for trainers. Ideally, experienced trainers are competent in an array of training methodologies, and trainers with less experience are paired with highly skilled trainers. Local or regional trainers familiar with the settings of the trainees are also highly desirable. An advisory group that represents stakeholders is a potential source for identification of qualified trainers. A common pitfall to be avoided is the selection of trainers based on seniority or rank rather than training skills.

The trainer orientation process focuses on training methodologies as well as content mastery. Providing practice sessions with peer “teach-back” opportunities can be an effective interactive learning exercise that enhances didactic content. Ideally, highly experienced trainers with content expertise orient the less experienced trainers. They can help guide the less experienced trainers on strategies for the use of training materials and mixed training methods, go over model sections of the curriculum that incorporate the various methods, and offer an opportunity for trainers to teach back course content and receive feedback. Extensive trainer preparation helps less experienced trainers feel more confident in their abilities, while increasing their personal investment in achieving a high standard of quality.

Selection of a training venue that affords adequate space and a comfortable learning environment for the target audience is another important component of successful training implementation. Off-site training prevents participants from being interrupted by clinical responsibilities but requires administrative involvement and planning for adequate staffing coverage. Staffing coverage is easier to facilitate during a regional training, which involves select participants from a number of regional health facilities, rather than situations in which large numbers of staff from a single program or site attend all at once. Additionally, on-the-job preceptorships not only provide opportunities to address the clinical application of training but also reduce the problem of staff shortages since training can be received while on the job.

Qualified trainers set the tone of the training experience by describing the plan for the training, ground rules, and time frame. Careful monitoring of time for each segment of the training, paying attention to participants’ verbal and nonverbal messages, and frequent check-in for understanding of take-away messages are key attributes of a good trainer. Clinicians attending PMTCT and pediatric HIV trainings are often overburdened by heavy workloads and inadequate staffing at their worksite. To be useful, training must realistically
Methods to Address the Gap between Training Programs and Clinical Care

The ongoing evaluation process serves to provide information about gaps that may exist between training programs and the actual delivery of clinical care. Training strategies that can be implemented to bridge such gaps include on-site clinical preceptorships and targeted clinician support tools and job aids for use in the work setting. On-site clinical preceptorships for PMTCT services pair experienced clinicians with trainees for periods ranging from a half day to a full week with the express purpose of providing guidance in the management of challenges presented by real patients in the clinical setting. For pediatric care, midlevel clinicians inexperienced in the management of pediatric patients in general or inexperienced in the care of HIV-exposed and infected children need more involved preceptorships over longer periods of time. Successful sites have a mix of experienced and inexperienced clinical staff. When this mix is not possible, weekly or semimonthly site visits by an experienced clinician—for the purposes of reviewing cases and addressing problems—can be critical to the ongoing delivery of high-quality services.

Targeted clinical support tools are user-friendly, accessible materials that address common problems that trainees will likely encounter (e.g., understaffing) and identify and discuss strategies to overcome those challenges.

Evaluation is an integral component of training. Evaluations conducted during initial or pilot trainings provide a way to obtain feedback that will inform the revision and finalization of training materials and presentations. The involvement of participants, trainers, and observers in the evaluation process provides diverse perspectives that are particularly useful. Course evaluations that assess attendees’ achievement of learning objectives and the usefulness of training activities help to determine whether the training has addressed the identified needs of the participants and can facilitate continuous quality improvement. Pre- and post-tests are also useful in that they help document both where training is most needed and the effectiveness of the training in addressing participant needs. However, pre- and post-tests cannot address all course content, and constructing valid test questions can be difficult. Therefore, this approach works best as one component of a broader, more comprehensive approach to training evaluation.

The tracking of process indicators (e.g., number, location, and role of trainees) monitors progress in developing capacity to deliver PMTCT or pediatric HIV services. Evaluations can also be used to measure progress toward provider competencies and to monitor and guide the clinical development of trained health-care workers. Midterm evaluations measure the extent to which training has resulted in sustained practice change on the job. Evaluation tools that measure to what extent learning is transferred to the clinical/work setting, and to what extent positive changes are maintained over time, are especially important. Long-term evaluations assess whether changes in health-care providers’ knowledge, skills, and behaviors resulted in positive patient outcomes.
DEVELOPMENT OF GENERIC TRAINING PACKAGES

The PMTCT GTP developed jointly by WHO and the U.S. Department of Health and Human Services–Centers for Disease Control and Prevention (HHS-CDC) is a useful focal point for a discussion of how generic training materials for resource-limited settings are developed. The PMTCT GTP includes trainer and participant manuals comprising nine modules, accompanying slides for each module, clinician support tools (i.e., pocket guide and wall charts), and a program and course director guide. Available in English, French, Russian, and Spanish, the GTP has been adapted for use in resource-limited settings in Africa, Asia, the Caribbean, and South America.

The GTP can be used in a number of ways to fully support or supplement national PMTCT training activities. Here are some typical uses:

- The GTP is fully adopted as the national package with minimal country-level input.
- GTP modules are used to supplement, update, and revise existing country materials.
- The GTP serves as a framework for a fully integrated package; extensive country-specific materials are developed to provide a comprehensive, cohesive national training package.

The GTP begins with an introduction and overview that provide an orientation to the teaching methodologies and a sample course schedule for the nine modules, which are as follows:

- Module 1: Introduction to HIV/AIDS
- Module 2: Overview of HIV Prevention in Mothers, Infants, and Young Children
- Module 3: Specific Interventions to Prevent MTCT
- Module 4: Infant Feeding in the Context of HIV Infection
- Module 5: Stigma and Discrimination Related to MTCT
- Module 6: HIV Testing and Counselling for PMTCT
- Module 7: Linkages to Treatment, Care, and Support for Mothers and Families with HIV Infection
- Module 8: Safety and Supportive Care in the Work Environment
- Module 9: PMTCT Programme Monitoring and Field Visit Guide

The successful dissemination and implementation of the GTP in more than 40 countries on three continents suggests that this training package meets diverse needs. The widespread use of the package points to the need for further investment in the development of generic training materials for resource-limited settings. A vital component of the success of generic training materials is the roll-out plan that provides a detailed description of a set of activities to engage potential users by introducing the materials, facilitating the development of an action plan, and providing technical assistance for implementing the action plan. The roll-out plan may include training exchanges and workshops targeting key countries preparing to scale up services.

The development of a national curriculum based wholly or in part on a generic training package begins with a decision by the ministry of health to lead the process. The first step entails identifying and convening a TWG comprising multidisciplinary stakeholders with expertise in PMTCT. Among these stakeholders are clinical experts, frontline care providers, program managers, and people living with HIV, in addition to a range of organizations (e.g., nongovernmental organizations, bilateral and multilateral partners, community- and faith-based groups). The role of the TWG is to provide leadership for the development of the training plan, the guidelines, the training package, and the monitoring and evaluation plan. The TWG
is responsible for regularly reviewing and updating PMTCT documents, establishing sustainable training strategies to effectively build capacity within the PMTCT program, and ensuring that policies and protocols are feasible and acceptable given the local cultural context.

The implementation of the GTP in a given country entails one of two related processes: adaptation or harmonization. In countries that do not have existing PMTCT training materials (or that have only limited materials), adaptation best describes the process that will be used. According to this process, the GTP serves as the basic working document, which is then amended to reflect country-specific information, such as national policies, protocols, algorithms, and program descriptions. For countries that already have training materials and established policies and protocols, the process used is harmonization. In this process, the national training materials serve as the basic working document and the GTP format is used to structure the material, address any gaps in the existing curricula, and ensure that all information is up-to-date.

Throughout both the adaptation and harmonization processes, the development of materials is under the supervision and guidance of the ministry of health, which identifies membership and assigns responsibilities to the TWG, the lead agency, partners, and stakeholders. The adaptation or harmonization of GTP training materials to meet national guidelines, resources, and needs can be described in an eight-step process, as shown in Table 2.

CASE STUDY #1: ADAPTING THE WHO/HHS-CDC PMTCT GENERIC TRAINING PACKAGE: THE KENYA HARMONIZATION EXPERIENCE

In 1998, the Network of AIDS Researchers in Eastern and Southern Africa (NARESA) PMTCT project was developed to conduct operations research that evaluated the feasibility of implementing a PMTCT program in three Ministry of Health (MOH) hospitals in Kenya. NARESA developed a curriculum for the pilot sites, and that curriculum was then used in the national scale-up of PMTCT from 1999 to 2004 to train 1,500 health-care workers. In 2000, the National AIDS and STD Control Programme (NASCOP) created the PMTCT TWG to facilitate and monitor PMTCT scale-up and implementation in Kenya. The TWG was charged with

- standardizing national PMTCT training materials and systems;
- establishing effective coordination of PMTCT programs;
- updating national PMTCT guidelines and policies;
- developing an operational plan for roll-out of PMTCT training for health-care workers; and
- implementing a sustainable trainee follow-up system.

The Kenya PMTCT scale-up plan led to the need for a service provider curriculum. Thus, the TWG was mandated by the MOH to harmonize the existing training materials (i.e., the NARESA pilot site curriculum) into a standardized national training package. Once NASCOP had created a draft curriculum, the CDC Global AIDS Program (GAP) training experts were invited to assist in the process of finalizing the materials. GAP training experts reviewed the content and format of both the original pilot site NARESA curriculum and the draft NASCOP national curriculum and presented a proposal for the integration of those two documents into a comprehensive, standardized national curriculum.

The CDC training experts invited the François-Xavier Bagnoud (FXB) Center at the University of Medicine and Dentistry of New Jersey (UMDNJ) to collaborate in the process of harmonizing the NARESA and NASCOP curricula with the PMTCT
## Table 2. Sample Harmonization Process for the PMTCT Generic Training Package

<table>
<thead>
<tr>
<th>Harmonization Step</th>
<th>Activities</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step 1: Prepare the curriculum outline</td>
<td>Analyze existing documents and training materials, comparing strengths and gaps with the GTP. From this analysis, prepare a list of proposed modules that identify key content and session topics.</td>
</tr>
<tr>
<td>Step 2: Develop a draft of the primary technical document</td>
<td>The primary document is usually the trainer manual, which ideally serves as the source for the participant manual and clinician support materials. If, as the trainer manual is developed, the TWG members do not have content-area expertise in vital areas such as infant feeding, testing and counseling, and antiretroviral management, that information is gathered in consultation with experts in those areas.</td>
</tr>
<tr>
<td>Step 3: Review and revise the trainer manual</td>
<td>The complete first draft of the PMTCT trainer manual is then reviewed by the ministry of health (MOH) and members of the TWG. This key step provides the opportunity to learn and build consensus on content. The trainer manual is revised based on the comprehensive review by the MOH and the TWG.</td>
</tr>
<tr>
<td>Step 4: Develop participant manual, accompanying slides, and clinician support materials</td>
<td>The participant manual can then be extracted from the trainer manual with an emphasis on conveying clear take-away messages with well-reasoned, easy-to-understand rationales for implementing the PMTCT program. Based on the needs assessment, job aids for clinicians, such as complementary pocket guides and wall charts based on trainer manual content, are helpful components of the training package.</td>
</tr>
<tr>
<td>Step 5: Pilot test the curriculum</td>
<td>For the pilot test, experienced trainers are selected and oriented to the training materials. In addition to the content review, the trainer orientation for the pilot test describes the roles and responsibilities of the trainer and the expected outcomes of the pilot test. The pilot-test participants are selected to represent multidisciplinary health-care workers with varying levels of PMTCT experience. Observers providing detailed evaluations of the pilot test are ideally key stakeholders planning to implement the national curriculum. Evaluations of the pilot test are completed, module by module, by participants, trainers, and observers, so that specific feedback can be collected for the final revision of the curriculum.</td>
</tr>
<tr>
<td>Step 6: Revise, finalize, and launch the curriculum</td>
<td>Careful analysis of the pilot-test data informs the revision of the curriculum. After final review and approval by the TWG and the MOH, the curriculum is ready to launch. A formal launch to present and promote the curriculum is an effective strategy to institute a national adaptation of the materials by multiple stakeholders.</td>
</tr>
<tr>
<td>Step 7: Monitor and evaluate</td>
<td>The monitoring and evaluation (M&amp;E) activities developed at the outset as part of the training plan are then implemented. Ongoing assessment of the training process, trainer competence, and participant knowledge and skills will contribute to the ultimate goal of effective delivery of PMTCT services.</td>
</tr>
<tr>
<td>Step 8: Provide follow-up training</td>
<td>Offering ongoing refreshers and supplemental courses helps to ensure the quality of PMTCT service delivery; the M&amp;E data drive the content of ongoing training programs.</td>
</tr>
</tbody>
</table>

Challenges and Lessons Learned

Through the experience of harmonizing the national training materials with the PMTCT GTP, solutions to some cross-cutting challenges have emerged (which are summarized in Table 3).

Lessons learned in the Kenya harmonization process include the need for consensus building among key stakeholders. To accomplish this, the MOH mandated that the PMTCT TWG and other content experts provide input on the technical aspects of the training materials. The TWG members worked collaboratively to build consensus on technical content. Another key concern in Kenya was the need to reduce the number of training days needed to adequately prepare health-care workers to deliver PMTCT services. The pilot test and subsequent implementation of the Kenya national PMTCT curriculum demonstrated that the PMTCT content could be delivered in a six- or seven-day course if conducted by a well-trained facilitator.

Successful harmonization experiences have emphasized the importance of trainer involvement in the development of training materials. Technical experts are crucial to the process, but they may include more material than is practical to communicate. Trainer involvement often results in more focused, pragmatic content decisions. In the training implementation process, it has been helpful to make the training materials available to participants prior to the training in a self-study format so that the training experience can focus more intensively on skills building so as to facilitate transfer of knowledge to the clinical setting. Given the multiple burdens on national governments and health-care workers in resource-limited settings, careful thought should be given to the development of training materials to ensure that they include practical tools and methods for negotiating the often challenging realities of the clinical setting.

**Table 3. Challenges and Solutions to Training Material Development**

<table>
<thead>
<tr>
<th>Challenge</th>
<th>Solution</th>
</tr>
</thead>
<tbody>
<tr>
<td>Creation of country-specific training materials</td>
<td>◼ Coordination among a representative, multidisciplinary group of PMTCT professionals to identify gaps between guidelines and practice and propose strategies to bridge those gaps</td>
</tr>
<tr>
<td>◼ Example: Integrating actual practices (that are often influenced by the lack of resources) with national and international PMTCT policies and guidelines</td>
<td>◼ Inclusion of clinic visits in the process of training materials development to learn the particulars of constraints encountered in the clinical setting</td>
</tr>
<tr>
<td>◼ Provision of more than one opportunity for training materials review prior to the pilot test</td>
<td></td>

**CASE STUDY #2: THE PEDIATRIC AIDS CLINICAL TRIALS GROUP/INTERNATIONAL MATERNAL, PEDIATRIC, AND ADOLESCENT AIDS CLINICAL TRIALS NETWORK GLOBAL TRAINING PROGRAM**

In recent years, a significant amount of HIV-related clinical research has moved from the United States and Europe to resource-limited settings. The significance of this movement for training in HIV care lies in the fact that while research is essential to ensure the safety and effectiveness of new therapies, site participation in research protocols can serve as one way to gain external support for the development of clinical care expertise through training. Sites cannot safely or ethically conduct clinical trials in the absence of a solid foundation of high-quality care that meets current international guidelines, and research networks can contribute to efforts to reach an acceptable standard of care.
When the Pediatric AIDS Clinical Trials Group (PACTG) network began establishing international sites in 2003, it was recognized that the network needed to direct additional support toward clinical training programs at research sites to support quality of care both within and outside of clinical trials. To establish a global training program that would support the development of clinical care infrastructure at research sites, PACTG initiated a collaborative agreement with the FXB Center at UMDNJ to lead the training effort. In 2006, the program was transitioned and reestablished as the IMPAACT Global Training Program.

The methods used to develop and implement training to support clinical care in the context of clinical trials allow blending of local, regional, national, and international expertise. A needs assessment survey consisting of a comprehensive list of skills and knowledge required to provide family-centered PMTCT and pediatric care, as well as to gain a general understanding of research, is distributed to a wide range of staff at sites before the scheduled needs assessment site visit. The survey serves as a point of reference to help identify site-specific training needs. Once the survey has been completed, there is an extensive discussion of survey results with site staff, and care and resources at the site are observed to ensure that the training plan addresses the unique needs and priorities of the individual site and utilizes local resources. Where expert resources for training do not exist locally, a regional approach to identifying program faculty is generally used to fill gaps in expertise. The regional approach benefits sites by helping to establish supportive connections among sites with similar resources and populations.

Challenges and Lessons Learned

The expanded role for nurses was identified as a common challenge among most of the research sites. In the United States, advanced HIV nursing practice is supported by the Association of Nurses in AIDS Care, which has a certification program for HIV nursing, and by the easy availability of government-supported education and training through the AIDS Education and Training Centers across the United States. In addition, U.S.-based nurses have greater access to graduate education programs, which allow for advanced training leading to a license to provide specialized services beyond the scope of the general nursing practice. In the PACTG global training program, this challenge has been addressed by careful mentoring of site research nurses and by providing training that includes content on training techniques (training of trainers), leadership, and in-depth coverage of the basic pediatric curriculum for HIV care and treatment.

Another challenge is the need to include training for the establishment and support of community advisory boards (CABs) for the research program. Training for CABs has included not only a basic overview of PMTCT and pediatric HIV care but also training on research methodology, research ethics, informed consent, and protocol review, as well as basic skills in meeting management, communication, and the overall role of community representatives in the research network. The effort to support the CABs culminated in the development of a 10-module training curriculum that specifically targets community representatives and covers all relevant topics. The curriculum makes wide use of clear and simplified language, graphics that support the training content, and interactive activities that solidify content while helping to build the CAB as a team.

*The HIV Prevention Treatment Network (HPTN) joined with PACTG to become the International Maternal, Pediatric, and Adolescent AIDS Clinical Trials (IMPAACT) network in 2006 as part of the restructuring of AIDS clinical trials networks by the National Institutes of Health.*
An important response to the challenges of this training has been the consistent use of a multidisciplinary training team. At a minimum, physicians, nurses, and community representatives are included, but the teams have often included social workers, psychologists, and pharmacists. This approach has been important in modeling a multidisciplinary approach to care and nursing leadership while sensitizing trainers and trainees to the skills, needs, and challenges of these various disciplines. All members of the training group are assisted in developing interactive learning strategies aimed at changing the actual delivery of care rather than just transferring knowledge. A strong mix of methods that include real case studies, community participation and input, panel discussions, role-play, and other interactive activities has been rated highly by participants in evaluation forms.

Outcomes
This project has provided 15 training programs at six research sites in South Africa, Zimbabwe, and Thailand, reaching more than 1,200 participants. Program evaluations have demonstrated significant knowledge gain, and comments from participants have been consistently positive. The multidisciplinary approach has changed the role of some of the nurses within the research teams to one of collaborative partner and group leader. Nurses have joined protocol teams and network committees, have demonstrated capacity and confidence in managing patients and families, and are contributing to training initiatives at newly established sites. The positive effect on community participation in the network has led to broader community support for research, a better informed and functioning CAB, a better informed community, and good relationships with community groups. Investigators have indicated that the program has helped them to gain support from clinical staff in the form of patient referrals, better communication about research participants who are seen or cared for by nonresearch clinicians, and a general sense of interest in and support for the research program among the health-care community. The success of the training program to date has made it possible to identify people who have been through the training program (including training-of-trainers courses) and have gained experience managing research patients who will then participate as trainers.

CASE STUDY #3: ENHANCING CHILDREN’S HIV OUTCOMES PROJECT, GAUTENG PROVINCE, REPUBLIC OF SOUTH AFRICA

Bringing pediatric HIV care to the community level presents specific training challenges in many resource-limited settings, including South Africa. Clinicians who provide HIV care and treatment in community settings are usually nurses, not pediatric specialists, and the complex care of HIV-infected infants and children is beyond their usual scope of practice. Training for existing child health professionals must offer new information and skills focused on the delivery of specialized pediatric HIV care and treatment (see Table 4, next page).

In addition, efforts to increase access to treatment and maintain and improve quality of care for HIV-exposed and -infected infants and children are often blocked by the severe shortage of qualified health workers.

The Enhancing Children’s HIV Outcomes Project
In November 2003, the South African government released the Operational Plan for Comprehensive HIV and AIDS Care, Management, and Treatment for South Africa (CCMT). Yet by late 2004 it was clear that few of the estimated 240,000 children living with HIV in South Africa were accessing treatment through the CCMT program, and the
The following examples of successful clinical mentoring through the ECHO program demonstrate the flexibility of this approach in addressing the unique needs and demands of diverse clinical sites and illustrate some of the challenges and lessons learned through this program.

### Challenges and Lessons Learned: Discoverers Clinic

The Discoverers Clinic, a private site supported by a charitable organization, is one of the sentinel sites for the ECHO project and has contributed greatly to the project’s success. Initially, the Gauteng Department of Health partners were skeptical of working together with a nongovernmental organization. At the clinic itself, there were major concerns as to how long the ECHO mentoring team would stay in the clinic and how ART services could be sustained once the ECHO team departed, given staff shortages and lack of clinic space. Counselors were very reluctant to counsel children, and all of the staff believed working with children would be more difficult than provision of HIV care and treatment to adults. The nurses, who had not received training in primary care or the IMCI, believed that their scope of practice did not include independent management of ART. But as is typical in resource-limited settings, the lack of available physicians demanded that routine care provided by nurses be expanded to include pediatric ART.

The majority of the children who were receiving treatment did so through the hospital-based antiretroviral therapy (ART) clinics linked to academic institutions. Through a situational analysis, it was determined that there was an urgent need to scale up and improve access to pediatric ART care and to increase the availability of ART at primary and secondary health facilities in communities where affected children and families live in order to address perceived barriers to pediatric ART service delivery. The ECHO project was officially launched by the Wits Paediatric HIV Clinics in October 2005 with support from a US$1 million annual grant from the U.S. President’s Emergency Plan for AIDS Relief. The aim of the ECHO project was to scale up pediatric ART, improve the quality of pediatric HIV care, and ensure the sustainability of services. The ECHO project uses a mobile clinical support team (MCST) model whereby teams from central academic sites strengthen more-peripheral facilities to provide care to the estimated 50,000 children living with HIV in Gauteng Province. The advantages and disadvantages of different approaches to training and capacity building, summarized in Table 5, were considered during the planning of this project (the table also includes insights gained through implementation of the MCST model).

Today, the ECHO project has expanded to support 13 accredited ART sites in Gauteng, three in Limpopo Province, and one in Mafikeng Province.

Source: François-Xavier Bagnoud Center, 2008.
this case, the clinic was able to add a nurse with the additional training, and she became the primary recipient of MCST assistance.

The initial skepticism and resistance of the staff quickly turned to optimism and openness when the ECHO team began seeing HIV-infected children with the primary care nurse and the clinic staff. The training at this site took the form of one-on-one case demonstrations and discussions, with a series of didactic lectures given every two weeks to the whole team. The primary care nurse also went to a tertiary-care hospital once a week for a period of six weeks to see patients alongside a mentor in that setting. The South African National Pediatric Guidelines for HIV Care were a primary focus of this training. Within months, the clinic’s nurse was initiating ART in infants and children with the weekly support of the MCST, and within a year she managed a stable cohort of children on ART with support provided by telephone only.

**Challenges and Lessons Learned: Taung Hospital in the North West Province**

The ECHO project started providing outreach support to Taung Hospital in October 2005. At that time, Taung Hospital was certified to provide ART and had an adult HIV clinic with more than 1,000 patients on treatment—no children were being treated at that time. The single physician at the site had not cared for a pediatric patient in more than 10 years. Due to the staff’s inexperience in treating children, basic pediatric care and phlebotomy had to be addressed before launching into HIV care and treatment. The nursing staff and the pharmacist were also new to pediatric primary care and needed training in basic skills. This case is an example of the advantages of the mentoring program, since the mentor team was able to adjust the training program to meet the unique needs of the site, rather than rigidly presenting a predetermined curriculum in a fixed amount of time.

At Taung Hospital, the ECHO MCST also visited with partners for adult care from the Reproductive Health Research Unit (RHRU) in order to create a linkage between that unit and the pediatric HIV clinic. This strategy helped to promote the family-centered model of HIV care and treatment and made it possible for RHRU personnel to provide relief staffing at the hospital, freeing the physician for training. To introduce the pediatric HIV clinic effectively, children and their caregivers were scheduled to be seen on the same day. This was made possible by coordinating visits by the RHRU and ECHO teams.

At each visit, the mentor gave didactic presentations before clinic sessions to highlight the basic approach to pediatric antiretroviral treatment and to address topics that the clinical team identified as needing clarification. The MCST counselor transferred skills to the on-site counselor through co-management of families and also helped the on-site counselor develop a system for addressing missed visits and patients that have been lost to follow-up. The training at this site took the form of one-on-one case demonstrations and discussions, with a series of didactic lectures given every two weeks to the whole team. The primary care nurse also went to a tertiary-care hospital once a week for a period of six weeks to see patients alongside a mentor in that setting. The South African National Pediatric Guidelines for HIV Care were a primary focus of this training. Within months, the clinic’s nurse was initiating ART in infants and children with the weekly support of the MCST, and within a year she managed a stable cohort of children on ART with support provided by telephone only.
every week, reserving only the most complicated cases to be seen alongside the ECHO team during its monthly visit. As of September 2006, ECHO support ended for the Taung clinic, but the team continues to hold a weekly family clinic.

The long distances patients traveled to access clinic services also posed a challenge at this clinic. They made it impossible to book the standard frequent appointments for adherence and clinical reviews following initiation of therapy. The team found that it was critical to mobilize the entire care team to make the most out of every visit in order to try and overcome the challenge of infrequent follow-ups. This has been a successful strategy. To date, the weekly family clinic cares for 109 pediatric patients on ART, and 104 of those children remain stable on treatment.

CONCLUSION
The first Global Forum on Human Resources for Health convened by WHO in March 2008 called for immediate and sustained action to resolve the critical shortage of health workers around the world, setting out the essential steps that need to be taken over the next decade to turn the crisis around. Chief among those measures was a call to all countries to give top priority to training health personnel from within their own country. Training is a key strategy for the scale-up of HIV services in resource-limited settings. Because frontline HIV health workers are already overburdened, it is essential to find and implement efficient strategies to ensure that they have the knowledge and skills to effectively provide much-needed PMTCT and pediatric HIV care services. Well-designed and executed training approaches can address the demands placed on health-care workers. The approaches and case studies in this chapter describe processes that have successfully addressed the training needs of frontline health workers. Development and adaptation of generic training materials has proven to be a valuable resource for efficient transfer of knowledge. Multidisciplinary on-site training teams and preceptorship experiences bridge the gap that may exist between knowledge and clinical practice. Health workers in highly stressful, resource-limited settings are the key to increasing access to PMTCT and pediatric HIV care services. Their willingness and commitment to take on these formidable challenges is a compelling motivation for the ongoing effort to develop creative, comprehensive training strategies and tools to meet the urgent need for training to scale up services.
REFERENCE LIST

Training and Clinical Mentorship to Support the Scale-Up of Pediatric HIV Care: Lessons Learned from Uganda

Edward Bitarakwate

Elizabeth Glaser Pediatric AIDS Foundation, Uganda

Despite the significant progress that has been achieved in Uganda in increasing access to combination antiretroviral therapy (ART), only about 9,200 of the 100,000 individuals receiving ART (9.2%) are children.\(^1\) This rate of treatment coverage falls short of the national pediatric treatment target of 15% of the total number of patients on ART. This rather slow scale-up of pediatric HIV care and treatment has been attributed to inadequate HIV diagnosis, poor access to care, and limited capacity to treat children. For instance, while HIV care is largely centered at referral health units, a majority of HIV-positive children seek care at lower-level health facilities. Another reason for the low proportion of pediatric patients in HIV care and treatment is the failure of health-care providers to systematically identify HIV-exposed or infected children.

Experiences in Uganda and other African countries show that even where basic resources for the provision of HIV care and treatment exist, providing health workers with formal didactic training alone does not significantly impact the total number of children who access care and treatment. A 2005 Ugandan national assessment highlighted limited health-worker skills as a key impediment to pediatric HIV care and treatment scale-up.\(^2\) Subsequent stakeholder meetings conducted by the Uganda Ministry of Health (MOH) produced recommendations in support of the decentralization of standardized basic training in pediatric HIV care and clinical mentorship in order to increase clinical staff capacity to offer pediatric HIV care.

The goal of the Ugandan clinical mentorship program was to build sustainable capacity for scaling up access to and improving the quality of pediatric HIV care and treatment. The specific objectives outlined to achieve this goal were (1) to enhance the application of classroom learning to patient care, (2) to support decentralized pediatric HIV service delivery and develop clinical expertise at lower-level health-care facilities, (3) to improve health-worker motivation by providing effective technical support, and (4) to maintain high clinical standards and practices through the provision of technical support to health workers. Key activities of the program included the creation of systems to support clinical mentorship, the recruitment and professional development of mentors, the completion of a needs assessment of participating programs, and the creation of an action plan, followed by the initiation of mentoring activities.
Monitoring and evaluation (M&E) activities were used to inform and improve the mentorship program, as well as to improve overall pediatric HIV care service delivery.

The principles and practices outlined in this chapter are based on the author’s experience with creating a clinical mentorship program for pediatric HIV care in Uganda.

**PRINCIPLES OF CLINICAL MENTORSHIP**

The World Health Organization (WHO) defines clinical mentorship as a system of practical training and consultation that fosters ongoing professional development to yield sustainable, high-quality clinical care outcomes. Mentoring should be seen as part of the continuum of education required to create competent health-care providers. The mentorship model used in Uganda is based on the existing hierarchy of supportive supervision within the district health services. Senior clinical and nursing staff based at regional hospitals and district health offices are targeted for enrollment as clinical mentors, who then offer practical training and consultation to health-care workers at lower-level health facilities. Through a process of training and retraining, these select groups of health workers progressively acquire HIV care and treatment expertise in aspects including, but not limited to, leadership and team building, training, M&E, and quality assurance (QA).

Focal persons within the regional HIV care and treatment team coordinate with and create linkages between the national- and district-level HIV care and treatment programs. Program activities designed by this team of clinical mentors form an integral part of the broader regional HIV-related work plans. Activity reports generated by the clinical mentorship team are then shared with the participating health facilities, the district health office, the MOH AIDS control program, and supporting partner organizations.

Figure 2 shows the technical hierarchy of ART services support in Uganda. Guiding policy at the national level allows for the organization of clinical mentorship at the regional level and its implementation at the district and health-center level.

The following considerations are crucial to the implementation of a sound clinical mentorship program.

**Planning and Coordination**

Key stakeholders must be involved in the development and adoption of a strategy for clinical mentorship within the host HIV care and treatment program.
A participatory approach at this initial stage builds ownership and commonality of purpose by incorporating views from a diverse range of interests, a key prerequisite for ensuring the successful implementation of national programs. In the Ugandan experience, stakeholder involvement was most successfully achieved under the auspices of the national AIDS control program through its pediatric ART subcommittee. A WHO regional working meeting on clinical mentoring held in Uganda provided significant incentive for the buy-in and launching of this process. A core group of organizations, including the Elizabeth Glaser Pediatric AIDS Foundation, the African Network for Care of Children Affected by AIDS (ANECCA), and the Pediatric Infectious Disease Clinic in Mulago then took the lead in planning, developing, and piloting a clinical mentorship program. This collaborative process among nongovernmental and governmental partners pooled the necessary resources required to initiate the pediatric HIV care and treatment mentorship program.

Central coordination of the mentorship program is necessary for promoting the adoption of new training approaches and formalizing their integration into existing health-service provision structures. By promoting clinical mentorship as a necessary component of pediatric HIV care and treatment scale-up, the MOH motivated and encouraged other development partners to buy in to this program. This central role also served as a pivotal mechanism for coordinating ongoing activities, sharing experiences, and continuously reviewing programming objectives to respond to emerging needs.

**Technical Support**

Technical expertise will be required at different levels during the development of a clinical mentorship program. At the national level, technical
Special expertise may be required to adapt existing M&E frameworks to include clinical mentorship activities. In a related process, health management information systems (HMIS) may need to be strengthened in order to effectively capture any gains in patient care outcomes resulting from clinical mentorship.

Long-distance technical resources and support could also be provided through telephone warm lines and Web-based discussion forums to enhance continuing medical education (CME) and real-time clinical problem solving at participating health facilities. The AIDS Treatment Information Center (ATIC), a referral network housed at the Infectious Diseases Institute at Mulago Hospital in Kampala, Uganda, utilizes the Internet and cellular phones to provide health workers with access to the latest medical information and advice to assist them with their treatment of patients. Through a toll-free phone service, contact visits, and the Internet, health workers are able to consult HIV experts in various aspects of patient management.

Human Resources Support

Clinical mentorship can only be provided where a minimum level of the targeted service is being offered. For example, clinical mentorship for HIV care can only be implemented at a health facility that is offering at least basic (or palliative) HIV care. In some instances, existing staffing levels at the participating health facility may not permit effective delivery of services. In such circumstances, it may be necessary to second clinicians, nurses, and laboratory staff to support either general or specialized HIV service delivery. Likewise, a given region may not have clinical staff with the basic qualifications for enrollment into the mentorship program. This would necessitate the recruitment or redeployment of additional personnel to initiate the mentorship program. Both these scenarios require the close support and cooperation of the local or regional
health authorities. Innovative approaches in which staff members are compensated for time contributed to clinical mentorship activities may attract regular short-term commitments.

Logistical Support
Once the mentorship program is developed, resources for national and regional roll-out should be mobilized. Development partners to the Ugandan national AIDS control program responded positively to a call to contribute resources to clinical mentorship programs in the country’s health districts. Start-up activities should be planned and provided for by the implementing organization. The assessment of programming needs at the district and health-facility level, the development of work plans, and the routine operation of clinical mentorship activities present significant logistic and financial requirements.

Where major resource gaps exist within the health-care system, the provision of essential commodities for pediatric HIV prevention, care, and treatment may need to be considered as part of overall support for clinical services delivery. Supplies of HIV test kits, materials for collecting dry blood-spot samples for DNA polymerase chain reaction (PCR) tests, cotrimoxazole for opportunistic infection prophylaxis, and antiretroviral drugs (ARVs) may need to be secured in order to ensure delivery of basic HIV services.

The development of regional health facilities into pediatric HIV learning sites, when feasible, should be considered. These relatively high-volume clinics can accommodate staff from lower-level health facilities during training attachments. Such training and exchange visits by health facility staff require financial and logistical support. For example, clinical mentor teams that are based at the regional level would require support for transport, communications, field allowances, office equipment, and training materials. The ability of the clinical mentors to conduct program activities, follow up on implementation recommendations at the participating health facilities, file reports, and undertake operations research requires significant logistical support for transportation, meetings, and other operating expenses.

ENSURING PROGRAM QUALITY
The following are some general guidelines for enhancing the quality of a clinical mentorship program.

Characteristics of a Good Mentorship Program
Mentoring programs should be well integrated within the existing service delivery structures to ensure their long-term sustainability. Long-term mentorship activities (i.e., lasting several weeks to several months) are generally more effective than short-exposure activities (i.e., lasting a few days per mentorship relationship). Built-in post-mentorship follow-up, with long-term, on-site supervision and/or backup by a competent health professional who is able to reinforce lessons taught during the initial mentorship exercises, often leads to better outcomes. Repeat visits by the same mentor are particularly reinforcing.3,6

A mentor’s familiarity with local issues and national and/or institutional HIV care and treatment guidelines and practice strengthens the program by shortening the mentor’s learning curve and period of adaptation. Mentoring activities carried out within the trainee’s usual working environment allow for more tailored advice and foster the adaptation of solutions to local conditions; this approach may be more effective than preceptorships at more sophisticated, higher-level facilities (i.e., centers of excellence). A balance between these two approaches is recommended in order to achieve the best results. Additionally, the mentoring of clinical teams has proven more effective
than the mentoring of individuals, who in turn are expected to influence their teams’ practices.3,6

There should be a well-defined process for coordination and communication between mentors assigned to the same site. Such a process can help mentors use experiences and lessons learned to collectively plan and/or refine their approach so that the mentoring program is specifically relevant to the mentoring site. Mentoring teams also must have the ability to relate clinical and process activities at health facilities to care and treatment outcomes. In this way, outcome data can be used to design or strengthen care interventions resulting in more favorable outcomes.

Characteristics of a Good Mentor
A good mentor should be at a professional level equal to or higher than that of the trainee in the same or a closely related field. The mentor’s practical clinical experience in pediatric HIV care and patterns of related comorbidities in the trainee’s (or similar) work setting should be extensive, and his or her knowledge base should be up-to-date. The mentor should also have proven experience in supervision, training, and team building, as well as an ability to work with people of diverse backgrounds and knowledge and skill levels. A good working knowledge of the trainee’s language as well as the language(s) used by the majority of clients further increases the effectiveness of the mentor.

In order to effectively plan for the training needs of prospective clinical mentors, it is necessary to assess their knowledge and skills for a given clinical service. In Uganda, a rapid survey was conducted through a self-administered, semistructured questionnaire. The rapid assessment explored mentors’ current levels of competence in the areas of clinical care, trainer skills, supervision, and clinical mentoring. This approach enabled program managers to identify critical aspects of the mentors’ technical and professional abilities that required development and/or strengthening. Upon completion of the assessment, short- and medium-term training plans can then be tailored to address specific gaps in mentors’ knowledge and skills.

LESSONS LEARNED: BUILDING A CLINICAL MENTORSHIP PROGRAM
The following discussion outlines the key considerations for building a quality clinical mentorship program. A list of required steps for program initiation is presented in Figure 3.

Ensuring a Sound Training Base
As a basic requirement, mentors must have sound knowledge and skills in a given field of clinical care. In the absence of a standardized national curriculum, there is likely to be limited coordination of training programs, making an objective evaluation of the mentors’ background training difficult. Based on the report *Rapid Assessment of Capacity for Pediatric HIV/AIDS ART Training,* the Uganda MOH mandated a working collaboration of key players in training, including ANECCA, the Elizabeth Glaser Pediatric AIDS Foundation, and the Pediatric Infectious Diseases Clinic / Baylor College of Medicine Children’s Foundation–Uganda. These partners were together charged with the planning and roll-out of the national training program in comprehensive pediatric HIV/AIDS care in Uganda.

In the first three months of the program, all prospective mentors participated in a course in advanced pediatric HIV care to ensure the same level of basic training. By enrolling the core group of clinical mentors from among a team of MOH HIV clinical care trainers, the mentorship program utilizes the experience of these persons to continually guide training improvement based on needs that are identified over time.

Training in advanced pediatric HIV care provides prospective clinical mentors with specialist
knowledge and skills for pediatric HIV care and treatment. Major areas covered include clinical treatment reviews and updates, practical clinical experience, clinic management (including patient flow), mentorship skills, and regional program development/planning. Additional advanced training in the form of regular clinical attachments to pediatric HIV centers of excellence ensures continuity of skills and knowledge acquisition for the clinical mentors. These attachments are also designed to provide mentorship to the regional clinical mentors by senior national-level HIV care experts, thereby ensuring the transfer of knowledge and skills to the district and regional levels.

An advanced training of trainers (TOT) workshop was developed to further enhance training skills among the participants. At the end of this course, participants develop and refine action plans for their respective regions. This approach serves to decentralize training capacity from the large cities,

Figure 3. Steps in the initiation of a clinical mentorship program

Step 1: Recruitment of a core team of mentors
Step 2: Pre-implementation site visit
- Meet with district health managers, facility administrators, staff looking after children (MCH, OPD, IPD), and staff providing HIV services. Introduce the objective of the visit (general). Invite staff to share what the health facility is doing in terms of HIV services delivery. Prompt about pediatric services specifically.
- Introduce the concept and objectives of clinical mentorship. Receive staff feedback and suggestions on modalities of implementation.
- Introduce the need for a rapid participatory “baseline” assessment to inform a facility-specific action plan (including provider training needs). Get a named facility representative to work with you—preferably one of the staff you will be mentoring.

Step 3: Rapid assessment
- Assess what HIV services are provided at this facility, by whom, and where (i.e., points of service).
- Assess access for children—entry points, mechanisms and volume of referrals, registration process, actual services provided, numbers of children in care, etc. (using a standardized tool).

Step 4: Analysis and action planning
Based on the findings of the rapid assessment, consider what can be done to increase and improve pediatric HIV care. This may include the following:
- Identification of children and families in need of services
- Timely diagnosis of HIV among children coming for other services
- Expansion of HIV services (care +/- treatment, referrals) currently offered for children and their families

Once these improvements have been determined, move forward:
- Set some simple targets.
- Define a clinical mentoring schedule to support the achievement of these targets.

Step 5: Initiation of mentoring activities
- Undertake initial introductory and planning visits with health unit management and care teams.
- Introduce mentorship tools.
- Institute monitoring and evaluation activities.
- Initiate quality-improvement mechanisms.
- Share best practices.
while the built-in follow-up mechanisms ensure that training activities translate into expanded and improved pediatric HIV service delivery.

**Policy and Strategy**

To ensure coordinated planning and implementation of mentorship activities, the roles and functions of the various levels of health service delivery must be understood. A clinical mentorship program should be designed to fit into a national strategy for HIV/AIDS control, including scale-up plans for HIV care and treatment services. The Uganda MOH national AIDS control program's pediatric ART committee prioritized the initiation of a mentorship program in order to directly increase access to quality pediatric HIV care. In addition, the MOH participated in the identification of the prospective regional mentors. This high degree of commitment at the national level enabled the integration of clinical mentorship activities into regional and district HIV/AIDS care programming.

**Human Resource Capacity Development**

A successful clinical mentorship program will be dependent on a skilled human resource base that includes the following components:

- Skilled, experienced, multidisciplinary team mentors
- Engaged and willing service providers to work with the mentoring team
- Consistent technical support for the mentor development program

This will require access to national HIV care centers of excellence and teaching institutions where senior pediatric HIV experts are found. Where local pediatric HIV care expertise is lacking, clinicians may need to be sourced from other countries. The mentors would also require periodic supervisory and monitoring visits from national-level program managers and pediatric HIV care experts. Additional technical resources might include resource materials (print, electronic, CME courses, etc.) and access to various forms of continued technical exchange.

**Logistics**

The clinical mentorship program should always work within the existing health system to avoid additional pressure on already overburdened public health services. However, additional logistics are needed to facilitate the movement of mentors to the various health facilities and the movement of clinical staff from lower-level health facilities to the regional referral hospitals for clinical training attachments. Mobile telephony could be provided as a practical means of efficient communication with and between different levels of health service delivery. Mentors should also be provided with training materials and job aids to establish and improve site-level systems to deliver pediatric HIV care and treatment.

**Monitoring and Evaluation / Quality Improvement**

An M&E framework and QA program are essential to ensure that the clinical mentorship program achieves its objectives. Ideally, these systems should be integrated with, and complementary to, existing M&E and QA systems within the national ART program.

The main goal of the M&E activities is to assess increased access and enhanced quality of pediatric HIV care services. In the Ugandan case, monitoring activities are scheduled as follows: monthly for health facility mentoring activities, quarterly for numbers of patients served, and semiannually for mentor development processes (e.g., training, individual evaluations). The focus of monitoring is on the numbers of individuals served and on qualitative aspects of the mentorship program (e.g., the establishment of a patient flow pattern that ensures the provision of adherence counseling
In Uganda, a collaborative effort between multiple development partners and the MOH has led to the development of a framework for a national clinical mentorship program as a part of efforts to deliver scaled-up prevention, treatment, and care infrastructure for children affected by HIV and AIDS. The Ugandan experience has shown that it is feasible to develop a clinical mentorship program based primarily on locally available human resources.

To date, 16 doctors from eight health regions within Uganda have been recruited into the mentorship program. This team of clinical mentors has participated both in training lower-level health providers on various aspects of pediatric HIV care and in the development and field testing of clinical mentorship tools. The national roll-out of a program for early identification of HIV-exposed and infected infants has been supported through the clinical mentorship program, and improvements have been noted in the quality of care offered to HIV-positive children.

The results of M&E activities can be used to inform and improve the mentorship program as well as overall pediatric HIV care service delivery. In this way, the clinical mentorship program provides an opportunity to strengthen existing national systems.

Developing National Training Materials for Prevention of Mother-to-Child Transmission of HIV: The Zimbabwe Experience

Agnes Mahomva, Anna Miller, and Rumbidzai Mugwagwa

PREVENTION OF MOTHER-TO-CHILD transmission of HIV (PMTCT)* is an important multidisciplinary public-health intervention. An effective national program will involve coordination among multiple programs (e.g., maternal and reproductive health, HIV testing and counseling, antiretroviral therapy (ART), immunization, nutrition, and other child survival initiatives) and various segments of the community (e.g., women, their male partners, infants, boys, girls, mothers-in-law, community-based organizations, etc.). Unfortunately, PMTCT has been implemented predominantly as a vertical program, with limited recognition of its multidisciplinary nature, and with minimal or no planned integration or links to other existing programs and the community. Appropriate training of PMTCT program implementers in several disciplines is therefore a key strategy that provides them with the necessary knowledge and skills for successful program roll-out. Development of materials for that training is a critical but complex undertaking. Although many generic PMTCT training materials have been developed to assist in the implementation of comprehensive PMTCT programs, use of such materials may be fraught with challenges.

LIMITATIONS OF INTERNATIONAL GENERIC AND LOCAL TRAINING MATERIALS

Existing international generic PMTCT training materials, such as those jointly produced by the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC), are evidence based, extremely detailed, and cover all the essential components of PMTCT. However, because of their generic nature, these materials contain few insights related to practical program implementation experiences unique to specific settings. Generic PMTCT training materials, by

*The term PMTCT appears throughout this chapter because it is a common term in the medical community and accurately describes the major physiological processes (in utero, intrapartum, or postpartum transmission via breastfeeding) that can cause children to acquire HIV infection. However, many community and advocacy groups use the term PPTCT (prevention of parent-to-child transmission) to avoid stigmatizing the mother and to emphasize the responsibilities of both the mother and her male partner. In fact, neither term accurately reflects the multidisciplinary nature of the combined interventions and support required to eliminate HIV infection in infants.
definition, cannot fully integrate specific training components from individual countries, including existing national policies and practices in the many established disciplines covered by PMTCT. These limitations compound existing challenges, such as the constantly evolving science relating to specific PMTCT interventions (e.g., antiretroviral drug use, infant-feeding practices to optimize HIV-free survival, etc.) and the multidisciplinary nature of its components. Thus, training materials must undergo frequent updates and cover the various disciplines that PMTCT encompasses. That means generic international training materials are often used only as reference materials, rather than as the basis for national training programs.

Adaptation of generic materials has been advocated for and shown to be possible in several countries. However, the process of adapting generic PMTCT training materials for practical use in specific settings has proved challenging. For the process to be feasible, program managers and implementers require training in adaptation methods. Adaptation experiences in Kenya have shown that while adaptation of WHO and CDC generic training materials was possible, an existing draft national curriculum was needed to hasten the adaptation process. In Ethiopia, adaptation of generic training materials was also found to be time consuming and required strong editorial and formatting assistance.

Both generic and locally specific training materials exist for most of the technical areas covered by PMTCT, such as ART and testing and counseling. However, the materials are often developed in many different formats, with similar information presented in different ways. In some cases, materials contain differing technical information and guidelines. The inconsistency, and in some cases redundancy, of training materials can result in individual health workers receiving several training sessions on the same information just presented differently. Consequently, learning and integration of information becomes difficult, and ultimately the delivery of holistic HIV prevention and care to women, their male partners, and their babies becomes problematic.

Because most PMTCT services are part of family and child health (FCH) services, existing national maternal and child health and reproductive health training materials should be used for PMTCT training sessions. The advantage of using existing local training materials is that they have been developed by the individual country, with country-specific health systems and program approaches in mind. Health workers are therefore already familiar with the materials and approaches. Given the relatively recent advent of PMTCT services, most existing training materials barely mention PMTCT and do not yet provide the detailed and comprehensive PMTCT content required for successful national program implementation and roll-out or comprehensive individual patient care. Thus, a lengthy process of revision and updating of existing materials, as well as the addition of materials that specifically focus on the integration of PMTCT with existing programs and health services, is necessary for successful PMTCT program scale-up.

This chapter describes Zimbabwe’s experiences in developing national PMTCT in-service and preservice training materials for facility- and community-based health workers. It also discusses the specific challenges associated with training materials development, summarized earlier, in the context of the Zimbabwe national health system.

**BACKGROUND**

Zimbabwe is situated in southern Africa and has a population of 11.6 million people. The country is divided into 10 health provinces and 60 health districts. The public health system is based on primary health-care services provided through rural health facilities, including primary care clinics and
district referral hospitals.\textsuperscript{5,6} Despite recent economic difficulties, Zimbabwe remains one of the more developed countries in sub-Saharan Africa, with an educated population and a well-developed transport and communication infrastructure.\textsuperscript{7}

The country’s health system has been greatly compromised by its declining economy. This has caused skilled health workers to leave the country in large numbers and has resulted in frequent stock-outs of drugs and other important commodities.\textsuperscript{8} Despite these challenges, the foundations of the national public health system have remained in place, including a district health system made up of primary health-care units and referral hospitals. The public health service is the lead provider of primary health care in the country. Nongovernmental organizations and other stakeholders also play an important role in supporting the system but do so only under the supervision and coordination of the Ministry of Health and Child Welfare (MoHCW). Zimbabwe’s health system has facilitated the introduction, implementation, strengthening, and roll-out of HIV/AIDS care interventions such as PMTCT.\textsuperscript{6}

Although the HIV prevalence in Zimbabwe has declined over recent years,\textsuperscript{9,10} the country continues to experience one of the world’s most severe HIV epidemics. At the end of 2007, HIV prevalence was estimated to be 15.6% among the adult population\textsuperscript{11} and 21.3% among women attending antenatal clinics (ANCs).\textsuperscript{12} Many initiatives and programs, such as the national PMTCT program, have been put in place in response to the scale of the epidemic.

\textbf{NATIONAL PMTCT PROGRAM ROLL-OUT}

Prevention of mother-to-child transmission of HIV has been identified as a priority intervention in the national fight against HIV/AIDS. The national PMTCT program was initiated as a pilot project between 1999 and 2001. National program roll-out started at the end of the pilot project period in 2001.\textsuperscript{6} By the end of 2005, the national program had expanded to 1,395 sites (approximately 98% of all health institutions in Zimbabwe). Roughly 70% of total reported births in the same year were to women attending ANCs where PMTCT services were available.\textsuperscript{13} These services were being offered as an integral part of ANC, delivery, and postnatal care services.

The MOHCW is the main provider of PMTCT services in Zimbabwe. However, many partners have collaborated with the MOHCW in providing PMTCT services at all levels. The MOHCW coordinates the participation of its partners through the national PMTCT Partnership Forum. Factors that contributed to the rapid roll-out of the national PMTCT program included the leadership of the MOHCW, the coordination of the national program, and the meaningful participation of local and international PMTCT technical partners in the national program roll-out activities, including production of standardized national training materials.\textsuperscript{11,13}

\textbf{THE ZIMBABWE NATIONAL PMTCT TRAINING PROGRAM}

The national PMTCT training program encompasses in-service and preservice training for facility- and community-based health workers (Figure 1, next page). During the early years of program roll-out (from 2001 to 2004), the main emphasis was on in-service training for facility-based health workers to establish health system readiness and provide a minimum level of service in as many facilities as possible, as quickly as possible. Community-based and preservice training were developed later, between 2004 and 2006.

The national PMTCT training program for in-service health workers is divided into two broad types of trainings: (1) general PMTCT training and (2) detailed trainings on infant feeding and rapid HIV tests. The five-day general PMTCT training is aimed primarily at midwives and all other nurses
and represents the cornerstone of training for the national PMTCT program. It covers all aspects of PMTCT, including an overview of HIV testing and counseling and infant-feeding counseling. Once all health workers at a facility have received the general training, that facility can register to begin providing PMTCT services, assuming all other logistics (e.g., laboratory and pharmacy supplies) are in place.\textsuperscript{14}

The widespread provision of general PMTCT training has been facilitated by a cascading training-of-trainers approach. The national training team is composed of key individuals from the MOHCW and implementing partners. First, these national PMTCT trainers are equipped with the knowledge and skills they need to train two provincial trainers from each province. Next, each provincial trainer trains two district trainers for each district in his or her province, and then the district trainers train health workers at the facility level with support from national and provincial trainers. An additional detailed six-day training on infant feeding and a three-day training on rapid HIV testing are provided by the national nutrition department and the national reference laboratory, respectively. These trainings are given to select nurses at registered PMTCT sites to ensure their capacity to perform rapid HIV tests and provide more specialized infant-feeding counseling for mothers living with HIV. In addition to employing the training-of-trainers model, the national in-service training program provides on-site training of mentors as well as on-site refresher training during supervisory visits and program review workshops.

DEVELOPMENT OF NATIONAL PMTCT TRAINING MATERIALS
The national PMTCT program expansion began in 2001, before standardized national training
materials were developed. In response to the need for standardized training materials, the MOCHW began developing comprehensive, national PMTCT materials for facility-based and community-based health workers; these materials were adapted for preservice and in-service training. The primary goal of the development process was to strike a balance between adaptation of existing materials (both local and generic international PMTCT training materials) and development of new materials. The steps of this process are outlined in Box 1.

Following are the steps taken in developing the national training materials.

1. **Hold a national consultation with provincial medical directorates (PMDs), program implementers, and key stakeholders.** At the end of the national PMTCT pilot project in May 2001, a consultation of PMDs and key PMTCT stakeholders was held on the roll-out of PMTCT. Participants were from all 10 provinces in Zimbabwe and represented various disciplines, such as health education, pediatrics, obstetrics, laboratory, nursing, drug control, epidemiology, nutrition, pharmacy, and health informatics. Local and international agencies in support of PMTCT in Zimbabwe were also represented. The main objectives of the consultation were to update participants on scientific advances in PMTCT and on the current situation regarding PMTCT policy and programming in Zimbabwe, and to obtain input from participants on strategies to support scale-up of the national PMTCT program. Key considerations highlighted during the consultation included (1) the evolving science relating to PMTCT programming and implications for care program roll-out activities such as training; (2) the need to recognize that provincial and district teams are the implementers of the national program; (3) the need for partners to actively support the national program; and (4) the need for the MOCHW to coordinate, take leadership, and empower the provincial and district teams to implement the national program. To assist implementers in carrying out the national strategy, a program plan and guidelines were developed, and tools, such as standardized training materials and monitoring and evaluation tools, were provided.15

2. **Define broad national PMTCT training requirements.** During the national consultation, detailed updates on the status of PMTCT programming in the country were provided by province- and district-level teams involved in the national PMTCT pilot program and general program expansion. Reports from the pilot sites noted

---

**Box 1. Steps in the Zimbabwe National PMTCT Training Materials Development Process**

1. Consult with provincial medical directorates (PMDs), program implementers, and stakeholders on national PMTCT program roll-out strategies, including PMTCT training.
2. Define national PMTCT training requirements based on
   - PMTCT pilot project evaluation report,
   - PMD and stakeholder consultation report, and
   - initial program roll-out experiences and lessons learned.
3. Develop national PMTCT training matrix plan: who gets trained, on what, where, and for how long.
4. Develop in-service national PMTCT training materials for facility-based health workers with technical and financial partner support.
5. Review and update community-based health worker training material.
6. Develop preservice training curriculum “road map.”

*All steps led by the National PMTCT Unit of the Ministry of Health and Child Welfare, with support from partners through the PMTCT Partnership Forum.*
that only a few health workers at each site were trained to implement the program. Nevertheless, the health workers who had not received PMTCT training were carrying out PMTCT-related activities, such as providing infant-feeding demonstrations and group health education to mothers at ANCs.\textsuperscript{16} This was an important finding because it demonstrated that all health workers in ANCs where PMTCT was being implemented needed training. That need was confirmed by several provinces that had started rolling out PMTCT services after the official national PMTCT pilot project had been concluded.\textsuperscript{3,13,15,16} Early experiences from the provinces not only indicated the need for all health workers to be trained but also highlighted the need to adopt comprehensive implementation plans that included specific PMTCT training requirements for the various health-care cadres.

3. Define specific PMTCT training requirements. A PMTCT program training matrix was developed in collaboration with provincial and district teams, together with their technical partners. The matrix was a simple written table outlining the various staff groups and cadres to be trained and the training type, content, and duration for each group.\textsuperscript{14} The matrix also indicated essential resource materials needed for each type of training. Once developed, the matrix was used to guide national, provincial, and district teams in making their comprehensive PMTCT training plans and in mobilizing training resources. The tool was also useful for guiding the process of developing national PMTCT training materials.

4. Develop an in-service PMTCT training manual for facility-based health workers. The first national PMTCT training manual was developed in haste at the end of the national pilot project in 2001, after national program roll-out had already begun. As a result, the manual had numerous gaps that were discovered during the initial phase of program expansion.\textsuperscript{6} Gaps identified included lack of comprehensive content on links with other HIV/AIDS programs and inadequate consideration of the implications of existing FCH training materials. Identifying those gaps during program implementation led the district teams and their implementing partners to call for revision of the manual.

The MoHCW, as the main provider of PMTCT services, led the revision of the manual and the subsequent process of training material development. PMTCT implementers and the PMTCT Partnership Forum technical subcommittee, as well as specialists in various disciplines such as ART, contributed additional technical expertise. The development process concluded with the production of a trainer’s manual for an integrated approach to HIV/AIDS prevention, care, treatment, and follow-up for pregnant women, their babies, and their families. The new manual addressed shortcomings identified in the first manual and accompanying implementation protocols. It covered emerging issues such as the science of PMTCT and the implications of ART roll-out on PMTCT service delivery, while incorporating existing national public-health and primary health-care approaches. Training on family planning and infant-feeding counseling was strengthened and integrated with recently updated national policies on infant feeding, including clear recommendations on exclusive breastfeeding and HIV. A new module focused on integrating PMTCT with cross-cutting programs and services and was based on experience gained from the first phase of the national program expansion. In that module, integration, links, and referral systems were clearly described in detail and with accompanying flowcharts. The flowcharts were based on reviewed and updated charts from the original national PMTCT implementation protocols, aimed at ensuring appropriate patient flow and referral of individual women and infants for ongoing care.
Once the training manual was completed, it was reviewed to ensure that all information presented was evidence based and in line with current national policy and practice. Existing health worker training materials in FCH, HIV testing and counseling, and ART were used as reference materials during the review process. Other supporting documents included reports from provincial PMTCT program review meetings, which highlighted gaps and challenges in the first edition of the training manual; local PMTCT guidelines and policy documents (i.e., the national procedures and logistics manual on PMTCT and the national PMTCT implementation protocols); and current WHO guidelines and generic PMTCT training materials.

As the comprehensive training manual was being developed, the national PMTCT program had already expanded to multiple maternal and child health-care facilities. The new manual was therefore organized into eight freestanding modules (Box 2), with various sessions under each module. That organization enables trainers to use each module individually during refresher courses and mentor-training sessions or as part of a complete general PMTCT training course. In a complete general PMTCT training, all modules can be combined and taught during a five-day program.

The draft manual was pilot tested at a refresher training-of-trainer’s course and was well received by the participants. Gaps identified at that training enabled the national PMTCT team to appropriately finalize the new manual. At the time of this writing, the manual has been in use at the district and provincial levels for a few months and further evaluation regarding the success of the manual is forthcoming.

5. Develop in-service PMTCT training materials for community-based health workers. One of the strategies identified at the national consultation on PMTCT roll-out was the need to mobilize communities to ensure better program uptake. Community-based health workers, such as traditional midwives, community-based family planning commodities distributors, village health workers, and home-based caregivers, play an important role in community mobilization and community support for national PMTCT program roll-out. Those cadres are normally managed and supervised by the MOHCW, together with its supporting units, such as the Zimbabwe National Family Planning Council. Community nurses (who are among the facility-based health workers trained using the national PMTCT training manual) are responsible for organizing and providing training and supervision to the cadres.

in their districts. In 2004, existing MOHCW training materials for community-based health workers were reviewed and updated to include appropriate PMTCT content. That was done by a technical working group composed of several community health nurses and technical specialists and partners in PMTCT. Modules from the newly developed national PMTCT training manual were used as reference materials. Financial and technical support for revising and updating the training materials came from implementing partners through the national PMTCT Partnership Forum.

6. Develop a draft preservice training curriculum or “road map.” The national PMTCT program recognized the need to review and update the existing preservice training curriculum for counselors, nurses, and doctors to include PMTCT content. The introduction of primary care counselors into the MOHCW structure during the expansion of the national PMTCT program provided an opportunity to ensure that the preservice training curriculum for the new counseling cadre included relevant and comprehensive PMTCT content. The national PMTCT team, with its PMTCT Partnership Forum technical partners, participated in the development of the preservice training curriculum for the new cadre. Training modules from the newly developed national PMTCT training manual were used as reference material to ensure that PMTCT content was consistent with that being taught to other health workers. The development of this curriculum was led by the National HIV Testing and Counseling Partnership Forum, composed of various local and international organizations supporting the MOHCW on HIV testing and counseling.

Discussions about updating and revising the preservice training curriculum for doctors and nurses to include PMTCT took place at the inception of the national PMTCT program roll-out. In 2005 the University of Zimbabwe’s HIV Quality of Care Initiative convened a stakeholder workshop to propose and initiate the revision of the preservice curriculum for health-care cadres, especially medical and nursing care cadres.17,18 The main objective of the stakeholder workshop was to review the existing curriculum and suggest updates on HIV/AIDS programs, including PMTCT. Key participants included the MOHCW technical and program officers and the university’s HIV curriculum working group.

The workshop participants were divided into working groups according to their specialties. The working groups focused on three key areas: (1) defining the minimum curriculum content; (2) determining the delivery process by looking at how it should be taught, by whom, and with what resources; and (3) determining how to evaluate students to ensure that they had acquired the necessary skills and competencies.18 At the end of the workshop, HIV/AIDS content, including PMTCT, had been included in the draft revised preservice curriculum for nursing and medical schools.

OVERCOMING CHALLENGES IN DEVELOPING TRAINING MATERIALS FOR PMTCT

Introduction, integration, and expansion of national PMTCT services within existing health systems requires comprehensive and well-developed training materials for various health care cadres. The consultative process used by Zimbabwe in the development of its training materials was a major challenge, primarily because of the large amount of time needed to get partners to participate at every stage of the process. Despite these challenges, meaningful participation and buy-in by the partners was essential, because the success of the national program roll-out relied heavily on their support.

Developing a comprehensive PMTCT training manual that could be used by various health-care
The economic constraints faced by the national program, as well as the limited human capacity at the national level, presented further challenges for the materials development process. The national PMTCT unit relied heavily on the financial and technical support of its partners for all the development steps (Box 3). The national PMTCT Partnership Forum assisted in mobilizing the technical and financial support needed through its Training Technical Working Subcommittee.

**LESSONS LEARNED**

- When developing national training materials, it is important to adopt a holistic and comprehensive approach by looking at broad and specific national program training requirements, and by looking at both in-service and preservice materials. Although difficult, addressing preservice training is likely to reduce the future costs (including opportunity costs) of frequent in-service training.
- Development of PMTCT training materials should address the needs of both facility- and community-based health workers. The process should consider the cross-cutting nature of PMTCT by looking at existing training materials; the implications of other HIV/AIDS programs, national policies, and approaches; and current evidence-based information on PMTCT.
- A national training matrix that provides information on who to train and what information to
include in the training is an important tool. The matrix not only provides an outline of the specific training requirements for each health-care cadre but also demonstrates the link between training materials development and a comprehensive national training plan. Using a training matrix also helps to identify gaps where new training materials are required.

- Developing training materials for a national program that has the involvement of many partners requires wide consultation. A consultative process is critical to involving the partners in using the materials and aids they have helped to develop.

- Participation of partners throughout the entire process provides meaningful technical and financial support. This participation increases stakeholder involvement in the national program roll-out and strengthens government collaboration with and coordination of all stakeholders. It also fosters program ownership by provincial and district implementing teams.

- Deeper integration of vertical ART and PMTCT programs is now required to maximize care for women and minimize HIV transmission to infants (e.g., via the provision of opportunistic infections services and ART within ANC facilities). Integration takes time but can be spearheaded through a comprehensive process of training materials revision that brings together leaders, managers, and implementers from both programs.

- Large amounts of content can be put into modular form to increase flexibility, simplify refresher training, help programs manage large numbers of trainings for in-service workers, and ease updating of specific sections as science and practice evolve.

**CONCLUSION AND RECOMMENDATIONS**

The process of PMTCT training materials development should consider the multidisciplinary nature of PMTCT by looking at existing training materials, the implications of other HIV/AIDS and maternal and child health programs, national policies and approaches, and current evidence-based information on PMTCT. The process should be practical and reflect the status and experiences of the PMTCT and ART program roll-out, the existing national health systems, and the public and primary health-care approaches. Above all, it requires collaboration and cooperation between key stakeholders, program leaders, and implementers at all levels to facilitate integration and enable successful service provision for women, infants, and families.

Expanding the Role of Nurses and Advanced Practice Nursing in HIV/AIDS Care

Suzanne Willard

Nurses are probably the best equipped to provide care to people living with HIV. The ability to develop a therapeutic relationship with the patient and to work with them over the long term is both the rewarding and draining part of working in HIV. With good medicines, there are more rewards than emotional drains.

—Carol Hutelmyer, RN, CRNP, advanced practice nurse with over 20 years’ experience working with people living with HIV (personal communication, October 2007)

The complexity of HIV disease management has necessitated greater provider collaboration and communication and a broader role for nurses in all aspects of patient care. While the expansion of all health-care provider roles and the evolution of their scopes of practice are inevitable in the context of HIV/AIDS, nurses are particularly well positioned to respond to the wide-ranging needs of people living with HIV. The demand for the expansion of nursing care driven by the increasing numbers of patients seeking care will continue to increase as HIV/AIDS programs are scaled up. For example, in South Africa it has been estimated that for every 500 people placed on antiretroviral therapy (ART), three extra nurses (one with advanced skills) and one extra pharmacist will be needed.1

The emergence of the HIV pandemic will surely be remembered as one of the critical points in history where nurses have made a significant contribution to public health. Nurses have many responsibilities in the clinical setting and many of these tasks can be shifted to non-nursing personnel. Task shifting is one strategy that provides opportunities for nurses to take a leadership role in addressing the pandemic. For instance, tasks such as attending on waiting areas, pulling patient files, and even checking vital signs need not be done by nurses (despite being common practice in many settings). Shifting these basic tasks to lower-level staff and training nurses in more advanced skills will permit them to focus on clinical care and the core components of nursing.

This chapter will outline the role of advanced practice nursing in HIV management and will discuss how the greater utilization of nurses overall can lead to improved outcomes.

INTRODUCTION TO ADVANCED PRACTICE NURSING

The health-care landscape in sub-Saharan Africa as well as other resource-limited settings has evolved significantly over the past decade. A particularly significant shift has been the renewed emphasis on the primary health-care model (with chronic care
as a key component) as opposed to the curative care model (i.e., treatment of acute conditions, such as malaria). The expansion of long-term care services for people living with HIV has brought with it the need for nurses to expand their role beyond the direct provision of care, to include the prescribing of medicines and the overall management of HIV/AIDS programs, including traditional training and the supervision of less skilled health-care workers.

Margretta Styles, a respected leader in the nursing profession, identified the four basic characteristics of advanced practice nursing as follows:

1. A specialized focus and population served
2. Expanded knowledge and skills
3. Complex clinical-practice challenges faced and clinical judgment required
4. Independent decision making

A nurse practitioner or advanced practice nurse is a registered nurse who has acquired the expert knowledge base, complex decision-making skills, and clinical competencies for expanded practice (see Box 1).

Many programs have proven that nurses can successfully provide high-quality HIV care services, including the prescribing of antiretroviral and other medicines. For example, in a study undertaken at 68 HIV care sites in the United States, Wilson and colleagues reported that nurse practitioners provided a similar quality of care to that of physician HIV experts, and a better quality of care than physician non-HIV experts.

An expanded role for nurses is not a new concept. Historically, nurses have often taken on additional responsibilities out of necessity, with little if any additional training or supervision, and nurses have always worked to meet the changing needs of their patients. Other practitioners also frequently take on expanded roles; midwives have long been recognized for their important role in maternal and child health, while clinical officers provide medical services in many settings where there is a shortage of physicians. In support of these expanding roles, the World Health Organization (WHO) has recently compiled recommendations and guidelines for task shifting that support an expanded role for nurses and other health facility staff in resource-limited settings.

The term nurse is in itself problematic, as it does not accurately describe an individual’s level of preparation; each country has differing guidelines for nurse preparation and educational programs, which can range from a one-year course to a three- or five-year program. Despite these differences, there are many nursing concepts that are common across all countries. At the most basic level, all nurses are trained to provide care and

---

**Box 1. Core Competencies of the Advanced Practice Nurse**

- Able to integrate research, education, practice, and management
- Demonstrates a high degree of professional autonomy and independent practice
- Capable of managing his or her own caseload
- Able to perform advanced health assessments and in possession of decision-making and diagnostic reasoning skills
- Possesses advanced clinical skills
- Able to provide consultation to other health-care providers
- Able to plan, implement, and evaluate programs
- Recognized first point of contact for clients

---
support to patients through the course of their illness. Vocational nurses, practical nurses, enrolled nurses, and registered nurses have all received some level of training in this area. Some of the more complex tasks related to patient care fall within the scope of practice of the advanced practice nurse. As such, the advanced practice nurse must have advanced skills in health assessment, clinical decision making, and expanded diagnostic reasoning.

In many settings, allowing nurses to prescribe medications can improve clinical outcomes and enhance the patient experience. For example, many developed countries have successfully adopted practice frameworks that allow nurses who are working in the field, regardless of educational preparation, to prescribe medications within the context of the scope of nursing practice. In developing countries, nurses occasionally do prescribe medications, but this is often done informally on an ad hoc basis. Often this need arises and is addressed before the educational system steps in to provide greater guidance. It is therefore essential that the responsibilities, training, rights, and roles of nurses relating to prescribing activities be clearly defined.

In 2004, the International Council of Nurses (ICN) created a framework for the involvement of nurses in drug-prescribing activities (Table 1). These models can be adapted to a range of settings in which there is a need to expand the current role of nurses beyond the direct provision of care.

### IMPLEMENTATION OF ADVANCED PRACTICE NURSING

Countries that have successfully adopted the framework of advanced practice nursing have done so by addressing a number of key issues, including legal requirements, such as needed approvals by government agencies and medical associations; development

<table>
<thead>
<tr>
<th>Prescribing Model Type</th>
<th>Practice Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial, independent, autonomous, or substitute prescribing</td>
<td>The practitioner is accountable for assessing the client; making a differential diagnosis; determining the appropriate medication, treatment, or appliance required to manage the client; and issuing the appropriate prescription.</td>
</tr>
<tr>
<td>Dependent, collaborative, semi-autonomous, complementary, or supplementary prescribing</td>
<td>The practitioner may prescribe as a dependent prescriber in collaboration with an independent prescriber, usually a medical practitioner, but without the need for direct supervision by the independent prescriber. The dependent prescriber is not usually responsible for the assessment and diagnosis of the client. This method is useful for issuing ongoing prescriptions after the initial prescription has been issued by the independent prescriber.</td>
</tr>
<tr>
<td>Group protocols or patient-group directions</td>
<td>The practitioner may supply and/or administer a named medicine in an identified clinical situation directly to groups of patients who may not be individually identified before presentation for treatment. It is not a form of prescribing.</td>
</tr>
<tr>
<td>Time and dose prescribing</td>
<td>The practitioner works within patient-specific protocols. Nurses are allowed to alter the time and dosage of particular medications. Again, this is not strictly defined as prescribing.</td>
</tr>

Guidelines issued by the U.S. Department of Health and Human Services (DHHS) now contain modified language that reflects the greater share of responsibilities being placed on nurses. For instance, the term health-care provider has largely replaced physician, acknowledging the role that nonphysician providers have in prescribing medications and in the provision of HIV care generally. WHO is also supporting various regional efforts aimed at developing policies that support the expansion of nursing roles and responsibilities; prescribing guidelines for nonphysician providers have been developed to assist in this effort. Médecins Sans Frontières (MSF) has also targeted nurses in its guidelines for drug management.7

Training and Education
The ICN recommends that advanced practice nurses receive a master’s-level education. However, of adequate training, supervision, and evaluation procedures; and the creation of effective referral systems for cases that lie outside the advanced practice nurses’ scope of practice6,9 (Box 2).

The ICN network for nurse practitioners and advanced practice nurses has recommended that countries interested in establishing a role for advanced practice nursing give attention to three key areas3:

1. Regulation—to monitor and protect individual practitioners and the general population
2. Professional training—to prepare nurses for higher-level practice
3. Ongoing professional and practical development—to assess and maintain the core competencies of advanced practice nursing

As highlighted earlier, WHO has begun to provide guidance for the task shifting now under way in many settings. Additionally, HIV treatment guidelines issued by the U.S. Department of Health and Human Services (DHHS) now contain modified language that reflects the greater share of responsibilities being placed on nurses. For instance, the term health-care provider has largely replaced physician, acknowledging the role that nonphysician providers have in prescribing medications and in the provision of HIV care generally. WHO is also supporting various regional efforts aimed at developing policies that support the expansion of nursing roles and responsibilities; prescribing guidelines for nonphysician providers have been developed to assist in this effort. Médecins Sans Frontières (MSF) has also targeted nurses in its guidelines for drug management.7

*Source: Adapted from Affara and Schober.*
in light of the current rapid scale-up of HIV treatment programs in many countries, educational institutions should be encouraged to develop programs that can prepare highly trained nurses in the least possible amount of time, while still covering the essential elements of quality nursing care.

Multiple factors affect the quality and breadth of education in advanced practice nursing. Certificate programs are perhaps the quickest path to establishing a curriculum and preparing a group of qualified individuals. Academic institutions, due to their complex structures, are generally slow to change established approaches to nursing education. Thus, it is important for leaders of academic nursing programs to be actively involved in quickening the pace of progress. Going forward, it will be important for expanded roles for nurses to be included in formal nursing preparation. If this can be achieved, an advanced degree beyond basic nursing preparation will provide further credibility and support for such a role.

Students selected for participation in advanced degree programs should be highly motivated, and their length of time as a nurse should not be the sole criterion; although clinical experience is important, these skills can be learned while nurses prepare for their roles in advanced practice. Nursing faculty should also be motivated to support expanded roles for nurses. Faculty can be creative in their approach to developing new programs of study and collaborate when appropriate with physicians and clinical officers in imparting needed skills. Those wishing to initiate an advanced nursing program can also collaborate with other universities that have had prior experience instituting such programs. Examples of successful partnerships established for this purpose include the relationship between the University of California, San Francisco (UCSF) and the University of Tanzania, and between the International Training and Education Center on HIV (I-TECH), the University of Namibia, and the Ethiopia Nursing Council.

Physicians can provide content and guidance for areas of practice that have traditionally been outside the scope of nursing. Faculty should be encouraged to teach in multidisciplinary teams to encourage the sharing of information and broader skill development. There should also be strong linkages between classroom education and practical, on-site mentoring. Practical training sites that are supportive of the development of nurses should be identified for this purpose.

Recommended core content for advanced nursing training includes the following:

- Core concepts and philosophy of nursing, including where nurses fit within the healthcare system and treatment framework.
- Scientific knowledge base—a deep understanding of anatomy and physiology, pathophysiology, pharmacology, nutrition, and family and social systems. Prescribing as part of treatment practice is critical. A key module in pharmacology is the teaching of medications and the importance of drug interactions. It is also important to be able to understand and interpret laboratory values and to be able to use these values, such as CD4 lymphocyte counts, to monitor HIV disease. This will form the most complex part of a nurse’s work.
- Physical examination—the ability to perform thorough physical examinations and to identify common conditions.
- Role implementation—an understanding of the scope of advanced nursing practice in the context of HIV disease management.
- Common management concerns. HIV disease management is not limited to pharmacology; therefore, knowledge regarding stigma, disclosure, substance abuse, and prevention issues should be highlighted.
THE UCSF ASPIRE NURSE TRAINING PROGRAM
By Catherine Lyons, Project ASPIRE, University of California, San Francisco

The University of California, San Francisco (UCSF) Positive Health Program’s international training arm, ASPIRE (AIDS Services, Prevention, Intervention, Research and Education), has provided training for nurses in South Africa, Zambia, Tanzania, Kenya, and Côte d’Ivoire. The program is based on the belief that many nurses in resource-limited settings have the required skills to adequately evaluate patients. Much as the transition from acute care to chronic care has required a rearranging of how care is provided (e.g., the introduction of longitudinal medical records), the shift in nurses’ roles requires both didactic training and clinical mentoring; in many cases, just a refresher course on skills that have not been actively utilized is required.

The overarching goal of the ASPIRE program is to enable nurses to independently manage patients. Expected outcomes stemming from this increased responsibility may include the following:

- Shifting of tasks from more highly trained to lower-level cadres of health-care providers and lay staff
- Down shifting of patients from central hospitals to regional, district, and local health centers
- Improving patient flow and efficiency of care
- Making the best use of professional resources
- Empowering nurses to practice at their full capacity
- Developing nursing expertise and independence in the area of HIV/AIDS care
- Developing a cadre of nurse leaders, mentors, and trainers

The ASPIRE program’s training is divided into two parts: classroom review and on-site observation and mentorship. The components of training are as follows.

1. Classroom review (utilizing case discussions and role play) of the following:
   - Medication side effects, identification of severe reactions, and treatment of minor side effects
   - Understanding the natural history of the disease, including the relationship between CD4 lymphocyte counts and opportunistic infections
   - Specific opportunistic infections and presenting symptoms
   - How to do a systematic review of symptoms
   - Basic physical exam, including pertinent vital signs
   - When to do a more extensive exam

2. On-site observation and mentoring of nurses, including feedback and correction as needed (may require two to five initial observations and regular follow-up observations)
The implementation of any new professional role is enhanced when experienced practitioners mentor newly trained workers. Mentorship provides these new workers with an opportunity to expand their skills and competencies beyond the formal training period. It is expected that the first groups of advanced nursing graduates will provide leadership to subsequent graduates. Mentorship should be built into any training program from the beginning. Since there is a great demand for these new skills, time and space must be allotted to ensure that experienced nurses will have the time and resources needed to mentor new groups of trainees.

Training is essential to protect and expand the practice of nursing as well as to ensure quality of care. Since the establishment of sufficient numbers of formal academic nursing programs is not feasible in many countries, innovative methods should be employed to fill the need for nurse training. Certificate programs, mentoring, and distance education are but a few of the methods that can be considered to support nurses in their work. For instance, I-TECH has developed several HIV/AIDS-focused training programs for nurses and other health-care workers in developing countries. These programs include on-site didactic (classroom) training as well as printed manuals, CD-ROMS, and videos that can be used together or separately to support quality HIV care. While access to technology such as cell phones and computers is still a challenge in many settings, the use of technology to enhance both training and practice can be highly beneficial.

The advanced practice role requires the support of the entire health-care team in addition to that of academic institutions and policymakers. There also needs to be active collaboration with more experienced clinicians. For instance, nurses will routinely need to have access to more experienced clinicians who can help them problem solve difficult or complex cases. As part of this process, a referral system should be established that provides patients with the benefit of easy access to quality health care as well as access to more experienced clinician opinions if their health status warrants. This clinical “backup” will require the use of technology and transportation assistance to ensure a seamless care model.

It should be noted that it is generally unwise to wait until adequate resources (e.g., graduate education programs) are in place to provide advanced training; advanced nursing practice is already occurring due to patient demand and limited human resources, and in these instances immediate training support is needed to ensure quality of care. Along with additional training, evaluation must be provided. It must be responsive to the changing roles of providers and should be ongoing in order to ensure that desired outcomes are consistently being achieved.

Professional Role Development

Nursing is emotionally challenging and labor intensive. Chronic HIV care requires the long-term, hands-on involvement of the care provider, with many difficult decisions to be made along the way. In addition to the detection of physical signs and symptoms and assessment of risk, every patient encounter is also an opportunity for counseling about HIV disease, treatment, infant feeding, family planning, and safer sexual practices. Quality management of HIV encompasses all these activities and demands that nurses be creative and comprehensive in their approach to care.

As nursing roles expand, there is also a need to develop innovative models of care provision to accommodate these new roles. For example, a unique model of HIV health services has been developed in South Africa—outside the government system—that utilizes a team consisting of a nurse practitioner, a pharmacist, and a physician. The clinic is located in a storefront inside
EXPERIENCES AND CHALLENGES AMONG NURSES IN MALAWI
By Evelyn B. Chilemba, Kamuzu College of Nursing, University of Malawi

THE AIDS PANDEMIC POSES GREAT challenges for nurses working as primary caregivers in high-prevalence, resource-limited settings such as Malawi. These challenges are due to a number of factors, such as staff shortages, limited resources, weak referral systems, and inadequate bed capacity in existing health-care settings.11

Nurses as primary caregivers of people living with HIV must possess the requisite knowledge and advanced skills to provide a broad array of care and support, including counseling services (e.g., nutritional and psychological counseling), prevention services, clinical management of HIV and other sexually transmitted infections, and the provision of antiretroviral therapy. But even with the proper knowledge and skills, the quality and availability of services may still suffer due to care being delivered in a hurried and sometimes careless manner because of inadequate staff and/or facilities.

Most clients depend on nurses to support them in a variety of ways beyond the direct provision of care. As a source of psychosocial support, nurses are crucial to sustaining patients’ sense of hope and, consequently, their adherence to therapy. Most people living with HIV also suffer from other chronic conditions that require specialized attention and care. In Malawi, the most common HIV-related conditions are tuberculosis, pneumonia, meningitis, diarrhea, and Kaposi’s sarcoma. When clients are informed of their diagnoses with these and other HIV-related conditions, they are counseled on lifestyle changes that can help them maintain adequate health despite the chronic nature of their illnesses. Yet even when a client has accepted the reality of his or her HIV diagnosis, the individual may still harbor feelings of sadness or anger. These emotions, if left unaddressed, can have a detrimental effect on the patient’s adherence to treatment, since the client may not yet understand or appreciate the need to continue taking his or her medications. In some instances, clients have even committed suicide due to lack of adequate emotional support.

Medical wards in high-prevalence areas are often overcrowded with HIV-positive clients suffering from various HIV-related infections. These patients tend to stay in the hospital for a shorter time than is recommended due to the limited bed space and shortage of human and material resources. Premature discharge of these patients can lead to further complications—even the emergence of life-threatening complications.

The nurse’s role is to instill hope in clients living with HIV to help them gather the will to live positively.12 When clients first learn that they are HIV-positive, they will require a great deal of support to help them cope with personal dilemmas, stigma, and other challenges. Individuals diagnosed with HIV experience a range of emotional reactions such as fear, guilt, shame, and uncertainty.13 Yet the shortage of nurses in most public health facilities in Malawi has resulted in minimal interactions between nurses and their patients, limiting
nurses’ ability to provide needed support and encouragement. These interactions are also an important opportunity to provide information on HIV/AIDS, correct misconceptions, and raise patients’ levels of awareness about important issues related to their HIV-positive diagnoses and the services available to them.^

A study among women receiving prevention of mother-to-child transmission (PMTCT) services at a provincial hospital in Kenya found that most clients had received inadequate information during patient interviews and treatment visits and could not recall information communicated to them during counseling sessions.^

Other studies have found that patients may drop out of PMTCT programs due in part to inadequate counseling.^

These findings reinforce the importance of freeing up more time for nurses to provide much-needed psychological support before, during, and after the provision of critical services such as PMTCT.

In Malawi, nurses following up with clients via home visits have noticed that stigma and discrimination can arise as a result of these visits. Frequent caregiver visits to a patient’s home can cause neighbors to believe that someone living in the home is HIV-positive. As a result, some clients may move to a different location without informing the nurses. This abrupt discontinuation of the nurse-client relationship can endanger the client’s health while leading to feelings of discouragement or burnout on the part of the caregiver. To address this problem, nurses in Malawi are working together with clients to devise ways to protect client confidentiality. Strategies used by nurses to date include not wearing their hospital uniform during visits, having the hospital vehicle drop them far from the client’s home, and planning visits so they do not occur at fixed times.

a shopping center, providing a convenient, “one-stop-shopping” site for health-care services. For South African regulatory purposes, the nurse practitioner is considered an employee of the pharmacist, but it is expected that all members of the team will work as equal partners. In this model, the nurse practitioner provides assessment, diagnosis, treatment, and care while the pharmacist prescribes and dispenses medications. The off-site physician is available for referrals and assistance with emergencies or complicated cases. This model was developed to enable efficient operation despite the country’s restrictive regulatory environment with regard to nursing practice. The success of this program has led South African regulatory authorities to consider less stringent limitations on nursing practice so that quality HIV care can be made more accessible. Such steps will need to be taken in many countries where health-care regulations, while protective of patients, have not kept pace with ever-changing patient needs and health-care realities. For this reason, advocacy is a necessary component of any strategy to expand traditional nursing roles, so that regulations are modified to support these changes.

Evaluation
Evaluation is an essential component of nursing practice. Evaluation of the advanced practice nursing role should be based on (1) clinical outcomes, (2) integration within professional circles, and (3) acceptance by patients/communities.
Nurse participation in the actual hands-on provision of care as well as the evaluation of these efforts is important, as nurses have significant ties to the communities in which they serve. The evaluation of nurses’ impact on patient outcomes needs to take into account the social, economic, and political components of health. HIV is a social issue as well as a medical condition, and as such requires a greater understanding of and sensitivity to the patient experience on the part of the healthcare provider. Implementing advanced practice nursing in HIV care requires behavior change on the part of nurses and other health staff, as well as an understanding of the social and cultural complexities that can arise when a patient is identified as being HIV-positive. Areas of focus for evaluation activities include access to and availability of services, acceptance of expanded nursing roles among patients and health professionals, cost of care, and quality of care.

Evaluation findings are important to advance the acceptance of task shifting and other needed measures. In the United States, several studies have examined the acceptance of advanced roles for nurses.4,17 A common finding was that patients’ acceptance of nurses in advanced roles increases as they have more experience with nurses in such roles.

Further research is also needed to analyze the impact of expanded nursing roles on clinical outcomes. For example, Bolton-Moore and colleagues18 reviewed clinical outcomes among children on ART in primary healthcare settings in Zambia, where the majority of care providers were nurses and clinical officers. Clinical outcomes measured included patient survival, weight gain, CD4 lymphocyte counts, and hemoglobin responses. The nurses received advanced training in ART as well as on-site mentorship. The study demonstrated that with appropriate training and mentorship, ART programs that rely primarily on nurses and clinical officers can provide quality care while efficiently utilizing available human resources. More studies like this are needed to demonstrate the potential of advanced practice nurses in resource-limited settings with high HIV prevalence.

**CONCLUSION**

In summary, there are four domains that impact the feasibility of an expanded role for nurses. The first is knowledge—do nurses have the information needed to provide quality care? The second domain is the validation of the role—is there support from other health-care providers for this role, and are there regulatory agencies that need to be involved? The third domain lies in the competency and skills of the clinicians—are the competencies needed to begin any new role clearly defined and can they be measured? Finally, the fourth domain to consider is the environment—is there a place within the health-care system for this new role?

HIV/AIDS has challenged health-care systems around the world. The impacts on science, research, and clinical care have been enormous, and the virus will continue to change the way we approach the management of chronic disease. In this changing landscape, nurses need to be vocal advocates on behalf of their patients and their profession. Nurses who choose to take on the advanced practice role will need to understand the importance of their voice and have the courage to use it. HIV care has evolved from the ground up, with nursing at the core of this framework. Nursing provides what few other health disciplines can: skilled professionals with the willingness and desire to develop long-term, therapeutic relationships with their patients. Such a commitment can be rewarding as well as frustrating. Implementing advanced nursing practice in resource-limited settings will help lessen these frustrations by matching skills and responsibilities as well as providing tools to improve patient outcomes.
While some policymakers may see this new cadre of advanced practice nurses as a short- or long-term solution to physician shortages, the nursing profession has never promoted advanced practice nurses as substitutes for physicians. Rather, this expanded role has been offered as a way to address the service gap that currently exists. Research and other public-health evaluations should carefully examine the health policy and other considerations that arise as this new approach is rolled out.

Acceptance by patients and other health-care providers, such as physicians and pharmacists, of the advanced practice nursing role is also key to the strategy’s success. There is much debate as to whether HIV care is a specialty that should be in the hands of medical specialists only. However, in areas where resources are limited and where there is an overwhelmingly high prevalence of HIV and other life-threatening illnesses, treatment can no longer be left in the hands of a few.

LABORATORY AND PHARMACY SERVICES
LABORATORY TESTING FOR HIV AND related opportunistic diseases plays a critical role in the effective implementation of prevention, care, and treatment programs with regard to disease screening, clinical diagnosis, staging of disease, therapeutic monitoring, blood safety, and surveillance. Because of this pivotal role, the overall goal of any laboratory program in a developing country should be to ensure sustainable, integrated laboratory capacity that can provide quality, rapid, accurate, affordable, and reliable diagnostic tests for the effective implementation of lifesaving treatment and prevention programs. However, because of a lack of access to reliable diagnostic testing and an acute shortage of trained staff, coupled with under-resourced laboratory infrastructure in developing countries, inconsistent diagnoses frequently lead to inadequate treatment, increased mortality, and inaccurate determination of the true burden and/or stage of the disease.¹

Since 2003, concerted efforts have been made to provide access to antiretroviral therapy (ART) to the approximately 40 million HIV-positive people residing in developing countries. These efforts include the United Nations–supported Global Fund to Fight AIDS, Tuberculosis and Malaria (GFATM); the World Health Organization (WHO) “3 by 5” initiative, which planned to provide ART to 3 million AIDS patients by 2005; and the U.S. President’s Emergency Program for AIDS Relief (PEPFAR), which has the goal of preventing 7 million new HIV infections, providing treatment to 2 million HIV-positive people living in targeted countries, and providing palliative care to 10 million HIV-positive people. Globally, the current state of laboratories in developing countries cannot support program needs. Indeed, the paucity of functional, quality laboratories—in terms of both human capacity and physical infrastructure—is uniform across most developing countries. Thus, from a public-health perspective, laboratory services must be significantly strengthened and expanded for these well-intentioned efforts to be successful. For laboratory services to be valuable in any program, they must be easily accessible and able to provide accurate and reliable results in a predictably quick turnaround time. The lack of laboratory services was highlighted in a survey conducted in 2000 by the WHO-sponsored African AIDS Vaccine Program (AAVP).² The survey revealed that, as of 2000, fewer than 10 countries in sub-Saharan Africa had the capability to perform...
HIV-1 RNA viral load or CD4 lymphocyte count testing. A similar survey performed by the WHO African Regional Office (AFRO) found out that although many countries were performing HIV serologic testing, only very few laboratories were enrolled in any form of quality control or external quality assessment (EQA) program.

In this chapter, we review the multiple challenges that hinder the smooth functioning of quality laboratory services in developing countries and argue that five key areas must be addressed in developing countries in order to develop sustainable public-health laboratories: (1) development of a national strategic plan that emphasizes the need for an integrated approach to disease diagnosis and monitoring—that is, a single laboratory should be able to provide diagnosis and monitoring for HIV/AIDS, TB, malaria, and opportunistic infections (OIs); (2) implementation of an effective tiered laboratory network for referrals; (3) ensuring better coordination of resources and partners in each country in order to avoid parallelism and to strengthen dialogue between research and service delivery laboratories; (4) advocacy for laboratory experts to be represented at all policy levels and during program design; and (5) establishment of a strong quality management system.

CHALLENGES IN PROVIDING RELIABLE LABORATORY SERVICES TO MEET PROGRAM GOALS

Finding and Training Laboratory Technicians and Managers

The systemic acute lack of qualified laboratory personnel is a major and severe constraint in implementing and scaling up HIV/AIDS prevention and care programs. In most developing countries, there is a clear correlation between the quality of trained staff and the relative distance from the capital city. National reference laboratories (NRLs) that are situated in the capital city tend to have more qualified staff than do regional or district-level laboratories. The severe lack of trained laboratory experts at the regional and district levels presents an additional layer of challenge in the rapid expansion and decentralization of prevention and care services to district health centers in areas where most of the population resides. To achieve rapid scale-up of services, the training of laboratory personnel is critical at all levels of the laboratory network.

Encouraging results have been reported by WHO AFRO. According to a survey conducted from 2003 to 2005, the number of laboratory staff trained annually in sub-Saharan Africa increased significantly at the district level. This increase suggests that countries are making substantial efforts to address the issue of the chronic lack of laboratory staff at the district level, in order to meet the huge demand for decentralized services. Training has also involved task shifting with nonlaboratory staff for some HIV laboratory testing services, such as rapid testing at the district level. In fact, nonlaboratory staff, if well trained, can task shift and perform less sophisticated laboratory testing at the district level, thereby allowing more qualified laboratory staff to focus on more sophisticated testing and the implementation of quality control and assurance programs. If appropriate standard operating procedures (SOPs) are established, nonlaboratory staff can be trained to properly and safely collect and handle samples, and either test them or ship them to regional and higher laboratories for complex analyses. The same WHO AFRO survey reported that the total number of nonlaboratory staff trained in HIV laboratory techniques increased from 387 in 2003 to 791 in 2005.

To address these staffing and training challenges, efforts are being directed to at least three areas: in-service training and the organization of
test-specific workshops to meet immediate needs, increasing preservice training that includes curriculum on the full spectrum of testing, and establishing a culture of effective quality management. Advocacy targeted toward universities and other training institutions is needed for effective incorporation of HIV-related content into laboratory curricula. Training must be accompanied by a strategy for recruitment and retention of staff in the public sector. In developing countries, considerable numbers of trained staff are currently being lost to the private sector and to developed countries. In addition, public sector health facilities should also ensure that trained staff members are not redeployed to other job functions where their newly acquired skills are not in use. Because the retention of well-trained laboratory staff is an integral part of total quality management programs, strengthening human resource capacity should be a major goal of building sustainable laboratory capacity.

As training programs are rolled out, it is important that each country develop a program for individual certification that establishes criteria for the successful completion of a standardized training program for both laboratory and nonlaboratory staff. Certification should evaluate trainees based on a written examination and a demonstration of competency in the relevant laboratory techniques. To maintain the integrity and quality of trainees, systems should be put in place for continued on-site monitoring of the competence of trained laboratory and nonlaboratory staff with respect to their ability to follow SOPs, including handing of samples, interpretation of results based on national protocols, and record keeping. Policies are also needed to deal with issues such as certification, training requirements, and necessary qualifications for personnel performing tests. This is especially important for HIV rapid testing and TB smear microscopy.

**Providing Reliable HIV Rapid Testing**

Reliable HIV testing is the cornerstone for meeting the health goals of prevention, care, and treatment programs in developing countries. To meet these health goals, millions of individuals must be tested for HIV infection, as knowing one’s status is critical to prevention. Since the early 1990s, several rapid tests have become available that detect HIV antibodies in 5 to 30 minutes and, when used correctly in the right algorithm, provide results that are as reliable as results obtained from using a combination of Enzyme-Linked ImmunoSorbent Assays (ELISAs) and Western blot (WB). These tests are less dependent on a cold chain, are easier to interpret, and do not require specialized laboratory personnel and equipment. Moreover, most materials needed to perform the tests are supplied in the test kit. Fairly recently, in response to the increasing need for HIV rapid testing, there has been a proliferation of new rapid tests produced by several companies from around the world. The number of commercially available rapid tests has increased at least fivefold, from an estimated 10 in 1995 to about 50 in 2005. Only 4 rapid tests have been approved by the U.S. Food and Drug Administration (FDA). Several rapid tests have been evaluated in Africa, and many tests have demonstrated sensitivity and specificity comparable to ELISA. However, there is a huge challenge in ensuring the quality and reliability of these new rapid tests as well as in ensuring lot-to-lot consistency. This requires a standardized and systematic assessment of the tests’ performance in order to determine their eligibility for use in programs. For this reason, providing appropriate guidelines and testing algorithms to ensure accurate rapid test results has been a priority for several institutions such as WHO and the U.S. Centers for Disease Control and Prevention (CDC). As a first step to ensure that only reliable rapid tests are used in PEPFAR programs, the CDC and the United States Agency for International
that have well-trained personnel and adequate procedures, and seldom in the peripheral laborato-
ries where their use is intended. New strategies and guidelines to ensure the quality of rapid testing are
needed to address these challenges.

Laboratory Clinical Monitoring
As ART programs continue to be scaled up in developing countries, CD4 lymphocyte count testing has
become critical in initiating and monitoring response to ART. The lack of access to laboratories capable of
performing CD4 count testing has led WHO to reccomend using clinical staging to decide whether or
not a patient should be initiated on ART. However, clinical staging does not always correspond to the
degree of immunosuppression. Several challenges account for the lack of wider use of CD4 cell counts,
even at central laboratories: (1) the high cost of flow cytometry, which is considered the reference method
of CD4 cell counting; (2) a lack of skilled laboratory staff; (3) the inability to maintain machines; (4) diffi-
culties in managing the supply of reagents; (5) a lack of reliable point-of-care and easy-to-use machines;
and (6) a lack of adequate quality assurance schemes to ensure reliable results. In order to address these
critical challenges, simplified non-flow-cytometric CD4 cell counting methods are being developed.

In each country, once rapid tests have been deployed, appropriate external quality assurance
measures are implemented. These consist of regular site visits, proficiency testing, and the retesting
of a small percentage of samples at reference or referral laboratories. However, having enough
trained personnel dedicated to site visits to review on-site testing where voluntary counseling and
testing (VCT), provider initiative testing, prevention of mother-to-child transmission (PMTCT),
and other programs are offered has been challenging in many countries. In addition, most countries
lack the capacity to develop a well-characterized panel for use in proficiency testing to monitor the
quality and performance of rapid tests at peripheral and district laboratories. The traditional practice
of retesting 5% to 10% of samples has not proven practical due to the large numbers of samples cur-
cently being tested. For instance, retesting 10% of two million samples in a given country can be very
taxing. In some settings, samples have been effec-
tively collected from district and peripheral labora-
tories and then retested. However, the results have
not been returned on time (or at all), thus prevent-
ing the tests from serving their intended purpose.
This is particularly crucial as many new rapid tests
are initially evaluated and approved in laboratories
Development (USAID) have developed a global panel of blood units that are being used to system-
atically evaluate the quality of rapid tests for use in all PEPFAR-supported countries. Second, the CDC
is working with WHO AFRO and other partners to implement postmarket surveillance to monitor
the performance of rapid tests once they are in use in the field and to evaluate lot-to-lot consistency.
This effort is aimed at ensuring that the quality and integrity of rapid tests are maintained at all times
as new lots of tests are released. Third, WHO, the
CDC, and USAID have developed a comprehen-
sive training package that provides guidance for
the deployment of HIV rapid tests in the field.

In each country, once rapid tests have been deployed, appropriate external quality assurance
measures are implemented. These consist of regular site visits, proficiency testing, and the retesting
of a small percentage of samples at reference or referral laboratories. However, having enough
trained personnel dedicated to site visits to review on-site testing where voluntary counseling and
testing (VCT), provider initiative testing, prevention of mother-to-child transmission (PMTCT),
and other programs are offered has been challenging in many countries. In addition, most countries
lack the capacity to develop a well-characterized panel for use in proficiency testing to monitor the
quality and performance of rapid tests at peripheral and district laboratories. The traditional practice

tively collected from district and peripheral labora-
tories and then retested. However, the results have
not been returned on time (or at all), thus prevent-
ing the tests from serving their intended purpose.
This is particularly crucial as many new rapid tests
are initially evaluated and approved in laboratories
Whether viral load testing will become widely available in developing countries in the coming years depends on the cost and complexity of the test. The WHO 2006 guidelines state that viral load testing may have a role in identifying failure and indicating when to switch medications in some patients. In addition, WHO supports wider access to viral load testing at tertiary laboratories. To fully address the issue of viral load testing to support the roll-out of treatment programs, cheaper and simpler viral assays are urgently needed. Until then, most treatments in developing countries will continue to be based on an invalidated public-health approach, but a continued push to make these and other technologies accessible to developing countries is necessary.

Some key partners and a number of well-known AIDS clinicians have argued strongly for the inclusion of viral load testing in the treatment of HIV patients in developing countries. However, in their present format, viral load tests cannot be deployed on a large scale in developing countries, especially at point-of-care sites. These assays must be performed by technicians well trained in virologic testing methods and require that venous blood be obtained, processed, and transported while frozen to the testing laboratory, with a turnaround time of eight hours. They also require a steady supply of electricity and large amounts of distilled water to run equipment that is usually very costly.

There is a consensus in the field that a suitable point-of-care viral load test should require no more than a finger stick of blood, with a single cartridge for testing and capturing results. The test should not require specimen refrigeration and the equipment should be able to run on batteries, with a cost of less than US$500 to $1,000 per instrument and US$5 to $7 per test. Results should be provided within two hours, and a health worker in the field with limited training should
be able to administer the test. Other options include blood draws and stable transport to referral laboratories where testing would not require the current level of sample integrity.

In order to meet the above requirements, it is conceivable that the way forward could be to develop a semi-quantitative test that would indicate the presence of a significant viral load over a certain threshold based on the intensity of a single test line. With this in mind, Dineva and colleagues have developed a prototype test that is based on a dipstick approach, which seems to produce viral load results as efficient as the complex, expensive, and instrument-dependent standard assays. However, such prototype tests require extensive validation before they can be used for clinical monitoring of patients.

**Assays for Toxicity in ART**

One of the causes of treatment interruption and subsequent failure among patients receiving ART is the acute and long-term toxicity that many of the drugs can cause. The monitoring of patients on treatment for HIV must also include routine clinical chemistry and hematology tests. Unfortunately, this is also a problem for many health facilities in resource-constrained countries, as very few laboratories are equipped to perform these assays. Guidelines are needed to establish the minimum tests that are required for the proper monitoring of toxicities. Again, the ideal situation for peripheral clinics in resource-constrained settings would be a strip-based assay that would allow simultaneous measurement on one strip for all the necessary tests for ART toxicities monitoring. Such an assay would work on whole blood and be electricity independent. This would be conceptually easier than developing simple solutions for CD4 and viral load testing, as most of these assays already exist in various formats on strips or are amenable to such a format.

**Resistance Testing and ART Treatment Programs in Developing Countries**

Because of the high cost and complexity of the HIV-drug-resistance assays, most developing countries lack the capacity to perform reliable testing for drug resistance. For example, in sub-Saharan Africa, drug-resistance testing capacity exists in only a few countries, including Cameroon, Côte d'Ivoire, Ethiopia, Kenya, and Senegal. As a consequence, it was clear at the start of the recent scale-up of ART programs that resistance testing would not be included as part of the laboratory test for monitoring patients on ART. Instead, what was implemented was monitoring HIV drug resistance at the population level and developing approaches to reduce its emergence and spread.

When WHO launched the “3 by 5” initiative in 2005 to expand access to treatment in developing countries, many critics were concerned that the large-scale use of ART drugs would lead to the occurrence of a drug-resistant HIV epidemic if the antiretroviral (ARV) drugs were not used appropriately. The impact of drug resistance on treatment programs can be enormous, as the transmission of resistant strains can lead to the need to develop new anti-HIV drugs and result in increased direct and indirect health costs. Thus, drug-resistant HIV strains have been recognized as a serious threat to the efficacy of current and future HIV treatment, although it is not clear how rapidly resistant strains will develop.

In countries where ART drugs have been used for many years, the prevalence of resistance among treatment-naïve subjects in several studies varied from 5% to 30%. A study carried out in Boston in 1999 showed a prevalence of resistance mutations of 18% in treatment-naïve HIV-positive people. More recently, a study conducted in Nigeria suggested that up to 17% of drug-naïve individuals carry viruses harboring drug-resistance mutations. Data from several European countries indicate that 10% of untreated HIV-positive patients had a drug-resistant virus. In sub-Saharan
Africa, the prevalence of drug resistance in treated populations has been comparable to that reported in Europe and the United States.23-25

Several major HIV-related public-health issues are being addressed by WHO, including the level of resistance to ART among prevalent HIV strains, changes in HIV-drug-resistance prevalence over time in different areas, and how adherence-enhancing interventions can slow the emergence of resistant HIV strains.26 WHO and its partners have laid emphasis on understanding the key determinants of resistance, especially adherence to treatment and factors that undermine it, while identifying ways to minimize the occurrence, evolution, and spread of drug resistance and providing information to international and country-level policymakers. WHO and PEPFAR are actively involved in the development and implementation of surveillance systems at national and regional levels. These joint efforts aim to measure HIV-drug-resistance prevalence among newly diagnosed and treatment-naive subjects. Monitoring systems are also being developed and implemented to measure HIV-drug-resistance prevalence among those treated. As part of its support for PEPFAR and WHO, the CDC is currently helping several countries conduct their threshold surveys, including Côte d’Ivoire, Kenya, Malawi, Namibia, Nigeria, Swaziland, Tanzania, Uganda, and Zimbabwe. WHO is establishing and strengthening a global network of experts and laboratories involved in HIV resistance testing and supporting technology transfer in resource-limited settings.

Several ongoing public-private partnerships are also addressing the issue of drug resistance in developing countries. For instance, Virco, a European pharmaceutical company, is actively involved in developing easy-to-use drug-resistance assays that can be deployed in sub-Saharan Africa. This company is a key commercial partner in an exclusive public-private partnership called Affordable Resistance Test for Africa (ARTA), which will receive a grant from the Dutch Ministry of Development Cooperation for the purposes of HIV-drug-resistance technology transfer.

**Early Infant Diagnosis**

Although WHO estimates that approximately two million HIV-positive people are currently receiving ART in developing countries,27 relatively few infants have received ART. As of 2007, the United Nations Children’s Fund (UNICEF) estimates that the percentage of infected infants in need of ART but currently not receiving it varies from 0.4% in Congo to 18.3% in South Africa.28 Determining the HIV status of infants has proven to be one of the most challenging aspects of PMTCT programs in developing countries. Clinical diagnosis is limited to identifying HIV-positive infants with symptomatic and/or advanced-stage disease and has a low predictive value for ruling out HIV infection in children who are asymptomatic but immunocompromised and in need of PI prophylaxis.29 Infants of HIV-positive mothers acquire HIV antibodies transplacentally and test positive for the presence of antibodies regardless of their actual HIV status. This transplacental transfer of HIV antibodies makes laboratory diagnosis of HIV infection in infants very complex. However, as maternal antibodies decay over time, most uninfected infants become HIV antibody negative by 12 months, and all are negative by 18 months. Thus, before 18 months, virologic tests are the only reliable means of detecting the HIV infection status of infants.29 Nearly 50% of HIV-infected infants under the age of two die before they can be diagnosed and effectively treated.29

Because of the lack of virologic tests in developing countries, access to accurate and timely diagnosis of infants has been a great challenge to the scaling up of early lifesaving pediatric treatment. Virologic tests are expensive and require more sophisticated laboratory facilities. Ensuring the accuracy of these tests for purposes of quality control and assurance...
is also expensive. More importantly, laboratory technicians specializing in virologic or molecular diagnosis techniques are in short supply in many resource-limited countries. Adequately trained technicians may have high turnover rates, as they are often sought by researchers and by other countries struggling to expand their capabilities.

Other challenges also exist. Phlebotomy of young infants requires supplies and skilled staff that are often unavailable outside large cities. Transport difficulties and distances make it impossible for whole blood samples to reach high-level laboratories in time and in good enough condition for accurate testing. Because of difficulties in returning results quickly to distant clinical sites, staff and mothers may lose confidence in a test and thus reduce its acceptability, while allowing results to go unclaimed. Despite the challenges, however, recent success has been realized using dried blood spot (DBS) nucleic acid polymerase chain reaction (PCR) testing.

**HIV DNA PCR and p24 Testing**

WHO recommends using HIV DNA PCR testing to diagnose perinatal HIV infection in exposed infants at their first immunization visit at six weeks after delivery. Although several commercial and home-brew methods for DNA PCR testing exist worldwide, the Roche Amplicor HIV-1 DNA test, version 1.5, has been shown to be highly accurate in detecting the multitudes of HIV subtypes that circulate in Africa and is currently being used in many programs across the continent.\(^{30-32}\)

The ultrasensitive p24Ag assay has been used by some groups for early diagnosis of HIV in infants as an alternative to DNA PCR testing. This quantitative assay is based on simpler technology that does not require the detection of the viral genome. Although some studies have shown a sensitivity and specificity comparable to that of HIV DNA PCR, the assay is not yet widely used because more validated studies are needed on its performance in different settings with different subtypes. In a recent study, false-negative DBS p24 results were associated with subtype D; the performance of DBS PCR was 84% for DBS p24 testing, 79% for DBS DNA PCR testing, 85% for plasma p24 testing, and 100% for plasma RNA testing.\(^{33}\)

Easy-to-use point-of-care virologic technologies are needed to support early infant diagnosis in resource-poor countries.

**Improved Early Infant Diagnosis Due to DBS Use**

DBS use has facilitated access to virologic diagnosis of HIV. Once the blood spots are thoroughly dried and stored with desiccant, nucleic acids in DBSs can be stable for several months at ambient temperatures. This feature of DBSs makes them ideal for transporting specimens from remote rural sites to a central or regional testing laboratory, thus allowing the creation of laboratory networks for early infant diagnosis. Although specimen transport remains challenging, networks of DBS PCR testing laboratories have been established in several countries, some based on the use of volunteers to transport DBS specimens to the nearest PCR testing facility. For instance, a strong laboratory network for DBS DNA PCR testing has been set up in Kenya. In Nyanza Province in western Kenya, 140 DBS collecting sites transport about 500 to 800 samples per month to the CDC-Kenya Medical Research Institute (KEMRI) laboratory in Kisumu for testing. The turnaround time for the KEMRI laboratory to return results to the collection site is two weeks. Similarly, the KEMRI laboratories in Nairobi provide PCR testing support to 37 sites in Central Province, while the Walter Reed Laboratory in Kericho serves 18 sites in Rift Valley Province (C. Zeh et al, 2006, personal communication). In Namibia, DBS PCR testing has resulted in a significant increase in the number of children diagnosed and placed on ART. With the support of PEPFAR, DBS PCR testing has been expanded to several countries within the last three years (Figure 1).
Several challenges still exist with regard to DBS use for early infant diagnosis. As programs expand, one obstacle has been the procurement and distribution of supplies for DBS collection. To meet scale-up needs and ensure consistency, it would be useful to distribute kits containing all the necessary supplies to health facilities. The precise contents of each kit for use in infant diagnosis or quality control of HIV testing would need to be determined individually for each country. Another challenge is the variety of DBS formats, some of which do not work properly. For DBS PCR testing laboratory networks to be effective, the relevant health-care staff must receive specific training in the collection, labeling, drying, and packaging of blood spots to ensure the quality of specimens for virologic diagnosis. Upon receipt at the testing laboratory, specimens must be evaluated by an experienced technologist using SOPs for rejection of samples. If more than 2% of specimens are unsatisfactory, staff at the site should be retrained in collection procedures.

Note: The Caribbean not shown on map

Figure 1. Expanding HIV-1 DBS-based early infant diagnosis in PEPFAR countries
away with the need for drying racks and separating paper. Because of this variety, it is often difficult for country program managers to determine which formats are appropriate for use. Most countries are currently using the Schleicher and Schuell (S&S) 903 specimen collection paper (Whatman) for DBS collection. An acceptable alternative to S&S 903 paper is Whatman FTA paper. High-volume laboratories may encounter difficulties in testing DBS specimens because extracting DNA from a DBS is labor-intensive and prone to cross-contamination. Further work in automating DBS punching and DNA extraction rather than replicating workstations is needed when testing large volumes of specimens, but with perseverance these programs can be very successful. Approximately 100,000 infants have been tested in the past 12 months and referred for appropriate treatment.

Setting Up Appropriate Quality Assurance Programs and the Need for Laboratory Accreditation

As indicated above, HIV prevention, care, and treatment programs have expanded very rapidly. However, laboratory infrastructure is still lagging behind in terms of the critical components of a quality management system (QMS), which is essential to the improvement of overall laboratory diagnostic services and provides a blueprint for sustainable quality testing. The basic concepts of a QMS must be implemented at all levels of the laboratory pyramid, including quality assurance for the testing process: (1) the pre-analytic phase, which involves competency of personnel, test selection, patient/client preparation, test requisition, correct labeling, transport of specimens, and safety; (2) the analytic phase, which includes specimen processing and storage, reagent preparation, preventive maintenance, quality control, method verification, test performance, proficiency testing, and safety; and (3) the post-analytic phase, which includes reviewing results and quality control, reporting test results and interpretation, and record keeping. In many developing countries, none of these three phases is being properly implemented. To implement an effective QMS, the country must have a laboratory policy that defines the needs and importance of accurate laboratory results. This remains a major limitation and is a gap that must be bridged as programs are scaled up in most developing countries.

In order to ensure that the current increase in resources leads to a significant improvement in laboratory services, standards-based strategies must be adopted in developing countries. This can best be achieved by making laboratory accreditation a critical element of the national laboratory policy and strategy. In sub-Saharan Africa, for example, the few laboratories in Ethiopia, Kenya, and Uganda that are accredited all use external bodies for accreditation and are supported mostly by externally funded research institutions. A standards-based strategy must include the continuing competency of testing personnel, quality management principles, routine audits of laboratory performance, and the customization of international standards that are applicable in-country. Each country could develop strategies and policies for accreditation of laboratories at all levels of the health system and create linkages with regional accreditation bodies that already exist or that could be set up and given the mandate to design regional accreditation schemes. Regional accreditation bodies could be set up along the lines of the existing regional economic communities in Africa, such as the East African Community (EAC), the Economic Community of West African States (ECOWAS), the Economic Community of Central African States (ECCAS), and the Southern African Development Community (SADC).
SANAS is recognized by the South African government as the sole national accreditation body giving formal recognition to laboratories. It is also recognized by the International Organization for Standardization (ISO), the international standard-setting body composed of representatives from various national standards organizations.

As an independent institution, SANAS is capable of evaluating laboratories with regard to their compliance with relevant international and national standards and assessing their competence to perform the tasks defined in their scope of duties. The accredited institutions’ tests, inspection reports, and certificates are recognized by other countries whose national accreditation bodies have reached mutual recognition agreements with SANAS. SANAS is currently represented on the major committees in the accreditation field and also participates in the assessments of other national and regional accreditation bodies. These linkages provide assurance that the rules applied to the SANAS-accredited system are as rigorous as those applied to other accredited organizations around the world. Because most countries in Africa cannot currently afford their own independent accreditation systems, a regional approach, such as the recently adopted WHO AFRO laboratory accreditation scheme, is likely the best strategy. In parallel, with international support, each country is assisted by implementation partners to strengthen its own accreditation body. In brief, laboratory accreditation should form the backbone of sustainable quality management systems.

Supply Management and Equipment Maintenance

In developing countries, it has been a challenge to ensure consistent supply and provision of laboratory commodities to meet the demand created by the rapid scale-up of programs. The timely availability of essential equipment, supplies, and reagents is critical to ensure the overall quality of laboratory testing and avoid disruptions in patient care. A system for the dependable and sustainable acquisition of high-quality reagents and supplies is urgently needed. When PEPFAR was created, USAID established a supply chain management system (SCMS) in order to standardize the procurement and distribution of laboratory commodities to support all PEPFAR countries. Moreover, WHO, the World Bank, GFATM, PEPFAR, the Bill & Melinda Gates Foundation, various countries’ ministries of health, and other stakeholders are working to build consensus on the best way to standardize laboratory commodities across programs and laboratory networks. Standardization of laboratory commodities offers a unique opportunity to coordinate the maintenance of equipment, bulk purchases, training on common instrumentation, and contract services mechanisms. Special attention must be paid to training service maintenance engineers in order to provide a network of biomedical engineers at all levels of the laboratory system. Critical to this aspect is the development of a national laboratory strategic plan that specifies the policies that govern laboratories at each level of a tiered system.
Laboratory Diagnosis of TB and OIs

TB accounts for about two million deaths each year, most of which occur in developing countries and are associated with HIV coinfection. Accurate laboratory diagnosis of TB is a challenge in developing countries for several reasons: a lack of trained personnel, inappropriate laboratory working environments, weak or nonexistent external quality assurance measures, a lack of referral systems for patient samples, a limited number of state-of-the-art laboratories to culture and perform drug susceptibility testing, and the creation of stand-alone silo laboratories. In fact, there are only two WHO supranational laboratories in Africa (one in South Africa and the other in Algeria). TB is the most common OI in HIV-positive people, and in some developing countries up to 40% of TB patients are living with HIV. Therefore, the need for accurate diagnosis of TB has become critical, especially as ART is being scaled up. Reports have shown that up to 40% of TB patients who are HIV-positive have smear-negative results. Moreover, in view of recent reports of extremely drug-resistant TB in South Africa, there has been an increased emphasis on strengthening laboratory capacity to diagnose TB in HIV-positive patients and on TB culture. Paradoxically, TB laboratories are some of the most neglected and understaffed laboratories in developing countries. However, some major programs such as PEPFAR have placed substantial emphasis on strengthening laboratory capacity to perform TB diagnosis in the context of HIV/AIDS care and treatment. As part of this PEPFAR effort, a regional integrated training laboratory center for HIV, OIs, and TB has been established by PEPFAR in Johannesburg in partnership with the leadership of the South African National Institute of Communicable Diseases (NICD). The NICD training facility will provide hands-on training for laboratory experts in all aspects of TB diagnostics, including smear microscopy, setting up EQA programs, specimen transportation, culture, and drug susceptibility testing. Moreover, this facility will provide integrated laboratory training to meet the needs of HIV, TB, malaria, and OI prevention, care, and treatment programs. Similar PEPFAR partnerships are being developed in other parts of sub-Saharan Africa. Challenges not specific to developing countries, but certainly more acute in resource-limited settings, remain for the diagnosis of TB in infants and young children, largely due to the difficulty of obtaining good sputum specimens from this age group.

Laboratory Information and Management Systems

As programs scale up rapidly, the implementation of laboratory information and management system (LIMS) technologies has become another major challenge. A LIMS is an integral part of a QMS and includes developing simple-to-use systems that allow for the tracking of samples at collection sites during testing and during delivery of the final results to the patients, and the archiving of leftover specimens. All of the above processes may occur in the same local laboratory, or it may be necessary for specimens to be transported across the laboratory pyramid in a network system to a reference laboratory for testing. Regardless of what approach is used, a well-defined laboratory system is needed to ensure proper specimen handling and efficient results reporting.

Because of the difficulties in implementing electronic software at all levels of the laboratory network, standardized, paper-based systems are needed at different levels of the laboratory pyramid in developing countries. In practice, source documents are too often handwritten pieces of paper or books that are sometimes retranscribed several times before reaching a patient or the clinical personnel providing care. This process creates many opportunities for error and resultant losses. In addition, accurate compilation of data for laboratory organization (such as assessment of needs) and for programmatic purposes is difficult.
Modern LIMS technologies have the potential to significantly improve data sharing across tiered laboratory networks in developing countries and to provide timely results at point-of-care facilities. Such technologies should be coordinated and supported—from the national public-health laboratory network to the peripheral laboratories. If such systems are implemented, they will not only improve the quality of clinical laboratory diagnosis but will strengthen the capability to provide epidemic alert and response by recording and analyzing essential laboratory data, maintaining and sharing the data in the laboratory network system in a standardized format, and facilitating frequent exchanges of information and surveillance data with other laboratories within the network and between countries. It will also facilitate a timely flow of information in the laboratory network, which will help inform policy- and decision-making authorities.

In the absence of a LIMS, a computerized system for the management of data, with entry performed directly from source documents, is highly desirable.

**Infrastructure**

In many developing countries, health facilities and laboratories in particular have significant infrastructural challenges. It is common to see facilities with minimal physical infrastructure, with even the physical building being inadequate for the needs of the laboratory. Moreover, laboratories, when they exist, are often in a degraded state. Significant investment in laboratory infrastructure development is desirable in these situations. This requires a concerted effort by government and external donors, preferably within a strategic plan. The chronic lack of clean running water and a stable power supply is an additional challenge that must be tackled while establishing adequate laboratory services and strengthening laboratory networks. Current infrastructure in most facilities also does not allow the development of adequate biosafety procedures in the laboratory and the health facility in general. The lack of proper waste management systems is a crucial problem encountered in many health facilities, where laboratory waste is often disposed of inappropriately, exposing patients, health workers, and the community at large to possibly dangerous infectious waste.

**Laboratory Automation**

Related to data management, it is also important to pay particular attention to the role of automated instruments in laboratory practices. Although the initial cost is high, these instruments often offer considerable reagent savings and allow laboratories to perform a much larger number of tests more reliably. As noted before, this is a more efficient and cost-effective approach than multiplying the number of workstations. The integration of these instruments in a LIMS is easier and increases the reliability of results by reducing human error, both in the performance of the assay and in the transcription of results. Unfortunately, equipment costs, maintenance issues, and operational problems limit the number of laboratories where these systems are feasible. Linking together LIMSs with regional laboratory automated systems enhances the quality of testing.

**The Way Forward for the Development of Sustainable and Quality Laboratory Capacity**

**Strengthening Sustainable Laboratory Health Systems through National Strategic Plans with Integration of Diseases in Mind**

We believe that to achieve the goal of sustainable laboratory infrastructure and services in developing countries, a well-thought-out and implementable national laboratory strategic plan is indispensable. A well-developed laboratory strategic plan should consider integrating the laboratory work required for at least the three major epidemic diseases: HIV/AIDS,
TB, and malaria, such that a laboratory at every layer of the health system can provide timely support for the accurate and reliable diagnosis, monitoring, and surveillance of these diseases, as well as a central national public-health reference laboratory.

Each strategic laboratory plan should address the specific situation of the country and the needs that must be met in order to support health programs and promote in-country capacity building. The plan would provide a platform for coordinating the efforts of all implementing partners and create a framework for advocacy and partnerships at the country level. Such a plan should be based on an integrated approach to laboratory infrastructure development that comprehensively tackles major diseases of public-health importance, such as TB, HIV/AIDS, and malaria. In addition, the plan should be based on a tiered laboratory network, with a strong role for a functional national public-health reference laboratory that is well linked to regional and district laboratory systems, so as to provide effective referral services. The plan should, however, make the effort to take into account and integrate the existing facilities that have been developed prior to the drafting of the plan, so as not to waste resources and the opportunities provided by these facilities. As outlined in Figure 2, the essential elements of an adequate national strategic

Figure 2. Cross-cutting elements for strengthening integrated tiered laboratory systems for HIV, malaria, and TB
labatory plan for an integrated, tiered network
include, but are not limited to, the following:
1. **Integration of laboratory needs for TB, HIV, OIs, and malaria, including diagnosis, treatment, and prevention.** Emphasis should be placed on strengthening laboratory health-care systems that can be used to respond to major infectious diseases of public-health importance. In fact, the current major drivers of disease burden in developing countries are HIV, TB, and malaria; therefore, laboratory capacity developed to address these diseases could invariably be used to fight other disease outbreaks. This approach would shift emphasis away from developing disease-specific laboratories (which are very often difficult to sustain due to a lack of adequate human resources) in favor of an integrated, tiered approach. Such an integrated approach would also allow for cross-training of laboratory staff and provide a unifying approach for EQA and task shifting.

2. **Definition of training needs and retention approaches.** This should include a well-laid plan for training, with strategic imperatives on preservice, service, and laboratory management adapted for the different laboratory system tiers. Retention strategies should include innovative approaches to improve laboratory-based jobs.

3. **Standards and policies for quality of laboratory services.** These include guidelines for certification and accreditation of laboratory personnel and services that address issues such as who is allowed to perform testing and at what level of laboratory tests should be performed, as well as guidelines on new technologies and their use in programs.

4. **Issues surrounding supply chain management.** These include standardization of laboratory commodities and equipment, as well as problems related to the cold chain and maintenance of equipment.

5. **Issues relating to laboratory safety and security.**

6. **A clear framework for working with all funding partners to avoid duplication and parallelism of efforts.**

### Developing Laboratory Capacity through Tiered Laboratory Network Systems

Strengthening tiered laboratory networks in developing countries is critical to meet program goals. HIV laboratory services should be integrated into general laboratory services (see Figure 3), which is not currently the case in many countries. Often HIV laboratories are either physically separated from routine laboratory services and/or use separate equipment and reagents.

### Developing Sustainable Laboratory Capacity by Leveraging Effective Partnerships and Coordination

Since 2002, multiple institutions and bilateral and multilateral programs have continued to provide generous funding to support programs and laboratory services in developing countries. However, generosity may be a burden if it is not well coordinated and managed by capable leadership. In most African countries, it is common for the World Bank, WHO, PEPFAR, the Clinton Foundation, GFATM, and private companies to work with the ministries of health to support laboratory capacity strengthening. If well managed through a national strategic laboratory plan and with coordination at the level of the funding bodies, this support can significantly strengthen laboratory capacity in a sustainable way.

Public-private partnerships could be established between funding bodies and private companies so as to allow them to develop low-cost, accurate, and rapid diagnostic tests that can be used at point-of-care sites to provide same-day results to patients. By eliminating the need for patients to make
multiple clinic visits, such tests would significantly improve the ability of patients to be monitored.

An example of leveraging resources is the effective partnership PEPFAR has established through the CDC Global AIDS Program together with four large not-for-profit medical societies that pursue exclusively educational, scientific, and charitable activities: the Association of Public Health Laboratories (APHL), the American Society for Clinical Pathology (ASCP), the American Society for Microbiology (ASM), and the Clinical and Laboratory Standards Institute (CLSI).

APHL provides consultations by senior laboratory professionals who direct or supervise public-health laboratories in the United States. The team members typically have 15 to 20 years of experience in quality laboratory system practice. APHL has the longest-standing laboratory cooperative agreement and is active in Angola, Botswana, Côte d’Ivoire, the Democratic Republic of the Congo, Ethiopia, Haiti, Kenya, Madagascar, Malawi, Mozambique, Namibia, Rwanda, Tanzania, Vietnam, and Zimbabwe. The association has taken on a variety of responsibilities and roles in these countries, but its primary efforts have been in national strategic planning, improvement of the infrastructure for laboratory referral networks, laboratory management training, and laboratory information systems. APHL has established links between state public-health laboratories and in-country services and fostered the training of senior staff as well as the development of local public-health laboratory associations. It has provided regional and country-specific management training to senior laboratory personnel in Ethiopia, Kenya, Namibia, and Zimbabwe, with an emphasis on quality systems management practices.

ASCP, which has a membership of more than 129,000 laboratory professionals, is active in Ethiopia, Guyana, Kenya, Lesotho, Swaziland, and Tanzania. It has also been requested to support in-service training activities in Nigeria and Rwanda. The primary focus of its support to countries has been in-service training in clinical hematology and chemistry. The organization has led in the development of a training-of-trainers (TOT) approach.
TIERED LABORATORY NETWORK SYSTEMS: THE EXAMPLE OF RWANDA

RwandA is often cited as an example of a country in Africa with a fairly developed tiered laboratory network system. In collaboration with foreign partners, the government of Rwanda has developed a network of laboratories across health systems in the country for the detection and confirmation of diseases of public-health importance such as HIV, TB, malaria, and other major outbreaks such as cholera. The national laboratory network system ensures that there is a pyramidal structure with a top-down and bottom-up approach. Thus, the NRL and the five university hospital laboratories constitute the first level of laboratory services, the district and private hospitals make up the second level of laboratories, and the third level of laboratories are those at the health centers (the bottom of the pyramid). At each level, there is a defined package of requirements, needs, and capabilities, accompanied by specific SOPs and testing abilities (Table 1). For instance, the NRL assumes responsibility for developing standards and coordinating laboratory activities for the different levels. To standardize the services offered at different levels of laboratories inside the national laboratory network, the NRL has established guidelines that define biomedical laboratory standards related to construction and basic supply requirements (e.g., equipment, reagents, and consumables) at each level of the laboratory pyramid (Table 2). The NRL also performs in-service training for laboratory technicians within the national laboratory network. These training activities are strongly supported by partners. The quality control and quality assurance activities are very well established at the NRL and cut across diseases. Because laboratory capacity for HIV/AIDS, TB, and malaria testing has been strengthened at the NRL and central level, the laboratory is presently armed to support the investigation of other outbreaks in coordination with other district laboratories. To ensure the quality of laboratory testing for HIV, TB, and other diseases, reports are submitted by the district and hospital laboratories to the NRL. Supervision and feedback are provided using a checklist, as applicable to the different levels. The NRL has an elaborate quality assurance program that includes, but is not limited to, HIV serology rapid testing, DNA PCR testing for early infant diagnosis, CD4 counts, and TB and malaria smears. As multiple partners such as GFATM, the World Bank, PEPFAR, and others continue to assist the country, consideration should be given to strengthening the following gaps: the shortage of skilled staff to perform specialized laboratory tests, the need for an improved laboratory information system, the need for creative ways to ensure proper sample referral, inadequate communication facilities, power outages, supply chain management and distribution of reagents and laboratory equipment, and disposal of laboratory waste.

to expanding these services from the federal to district levels in Ethiopia, Kenya, and Tanzania. In Lesotho and Swaziland, it has been integrally involved in strategic planning for public-health laboratory services. In Ethiopia, it is partnering with Joint Commission International to establish national standards for laboratory accreditation.

ASM is the oldest and largest single life science organization in the world and the largest publisher of peer-reviewed professional journals. Consultants are chosen for their technical and cultural expertise from among the society’s more than 43,000 active members worldwide. The partners are currently providing technical assistance in the following areas: laboratory networks, laboratory information systems, accreditation, pre- and in-service training, general microbiology, development of protocols, laboratory management, chemistry and hematology, and quality assurance. ASM is actively supporting programs in Côte d’Ivoire, Kenya, Mozambique, Namibia, Nigeria, Zambia, and Zimbabwe. Its primary focus to date has centered on the enhancement of services for TB and other OIs. In this capacity, the organization is working closely with the ministries of health, WHO, and in-country implementing partners. Its activities include in-service training and infrastructure support for basic microscopy, TB culture and resistance testing, and assistance to countries in strategic planning for laboratory services. In Zimbabwe, ASM is also working with the ministry of health to standardize clinical microbiology protocols on a national scale and expand quality assurance measures at all levels. Work in Kenya, Namibia, and Zambia was initiated during the first year of the cooperative agreement, and activities in Côte d’Ivoire, Mozambique, Nigeria, and Zimbabwe were initiated this year.

CLSI, which writes and distributes guidelines for best practices in the field of medical laboratory testing, is the convener of the ISO’s 52-national-member committee on medical laboratory standards. CLSI has been active in Tanzania and Zimbabwe and has recently started to work in Ethiopia and Nigeria. CLSI is working with countries to align national practices with the ISO’s international standards for laboratory accreditation. In this capacity, the organization is participating in workshops to develop SOPs and train laboratory staff in the documentation of these procedures to be maintained in laboratories. It will continue these activities in both Ethiopia and Nigeria. CLSI is also working with ASCP and Joint Commission International to promote clinical laboratory accreditation by developing a stepwise approach for aligning laboratory standards with ISO guidelines at all service levels in resource-poor settings. This effort is focused on identifying specific steps that can be taken in training, record keeping, specimen handling, and laboratory management at each service tier that will facilitate progress toward accreditation and establish national norms.

Collaborations are also in place with WHO Geneva, WHO AFRO, and the Clinton Foundation. These strong partnerships have led to joint laboratory guidance, including the following:

- Guidelines for Appropriate Evaluations of HIV Testing Technologies in Africa
- Guidelines for Using HIV Testing Technologies in Surveillance
- Guidelines for Assuring the Accuracy and Reliability of HIV Rapid Testing
- Manual for the Laboratory Identification and Antimicrobial Susceptibility Testing of Bacterial Pathogens of Public Health Importance in the Developing World
- A comprehensive training package for HIV rapid testing

PEPFAR also maintains close collaboration with the Clinton Foundation and WHO AFRO to develop guidance on facility-based laboratory management and safe laboratory practices.
Advocacy for Laboratory Experts in Policymaking and Program Planning

Strengthening laboratory medicine in developing countries must be seen as an integral and critical step toward improving overall health-care systems. To achieve this goal, laboratory leaders should be trained and laboratory departments should be created within the ministries of health in developing countries and supported with defined budgets. Strong leadership within the ministries of health will ensure that laboratories do not remain an afterthought in the process of strengthening health systems. Another area that needs much attention is greater laboratory involvement early in the planning stage of program design. Often, laboratory input is sought only after program managers’ planning is quite advanced or near the execution of activities. In addition, due to the complexity and specificity of laboratory activities, infrastructure development, equipment installation, training, and initiation of operations generally require more time than many other aspects of a program. This usually leaves the laboratory lagging behind other components of the program and limits its ability to provide useful insights and contributions.

CONCLUSION

With increased resources to fight HIV/AIDS and related diseases, laboratories in developing countries are now faced with an opportunity. We can collectively take advantage of the increased resources currently available for global health to expand programs and strengthen laboratory services. A coordinated approach using a national strategic laboratory plan could provide a vehicle for meeting this goal, which would contribute significantly to the development of overall health systems. While directly facilitating the prevention, care, and treatment of HIV disease, better-quality laboratories that are developed to support the roll-out of HIV/AIDS programs can also be important in the fight against other emerging or reemerging infectious diseases and would provide future capacity to support clinical trials for HIV/AIDS, TB, and malaria programs. The increase in resources may present a challenge if efforts are not coordinated, resulting in the emergence of parallel laboratory systems that may lead to the collapse of fragile national laboratory systems and undermine the goal of sustainability. Moreover, if the quality of laboratory services is not improved as quickly as possible, program managers may not see the usefulness of laboratory testing in the overall arsenal of global health protection measures. The key to achieving a sustainable laboratory-strengthening effort is for each country to develop a national laboratory plan that integrates the testing required for the prevention and treatment of all diseases of major public-health importance. Such a national plan will help donors and implementing partners identify where and how to support the ministry of health’s laboratory goals.
REFERENCE LIST

LABORATORY INITIATIVES THAT support the prevention and treatment of HIV and associated opportunistic infections are a critical component of any successful national response. Despite this fact, laboratory activities are generally not assigned the same priority as clinical site development.1 Historically, little emphasis or investment has been put forth for laboratory capacity development2-4 and the importance of laboratory diagnosis is often underestimated by clinicians and other decision makers. For instance, numerous examples can be found in the literature where the clinical diagnosis for a common infectious disease is not sufficiently sensitive or specific.5 More recently, organizations such as the Centers for Disease Control and Prevention (CDC), under the Global AIDS Program (GAP), have assisted resource-limited countries in developing laboratory capacity and infrastructure.6 Yet these improvement efforts are complicated by the fact that laboratories in Africa are increasingly being used to support internationally initiated clinical research trials for HIV prevention and vaccine development.7

Although substantial variation exists within and between countries, the overriding feature of laboratory programs in sub-Saharan Africa is a general lack of resources, including funding, facilities, equipment, and skilled staff.12 Due to the significant differences in laboratory capacity among different countries and between regions within a single country, a universal laboratory solution is not feasible; approaches need to be tailored to the region and the local disease epidemiology.8,9

Few laboratory services within African countries are coordinated under a single regulatory authority. One exception is South Africa, where the National Health Laboratory Service (NHLS)4 coordinates all laboratory activities within the public sector and the South African National Accreditation System (SANAS)5 has been appointed to ensure certification of laboratories according to internationally and nationally accepted “good laboratory practice” standards. Unlike countries such as the United States, where clinical testing is conducted in highly regulated environments according to Clinical Laboratory Improvement Amendments (CLIA) guidelines7

(using only assays approved by the Food and Drug Administration [FDA]), clinical testing in developing countries is often unregulated. Additional challenges arise from the fact that many laboratories within the African region are established by external funding agencies, often with little coordination between different funding organizations. This results in significant duplication in a region where consolidation of resources may be far more practical.

This chapter presents the accumulated experiences of a core laboratory support group established in Johannesburg, South Africa, to assist laboratories in embarking on HIV treatment initiatives, the evaluation of HIV vaccine candidates (funded by the International AIDS Vaccine Initiative [IAVI]), and clinical research efforts (such as those sponsored by the Bill & Melinda Gates Foundation, CDC, and the Microbicide Development Program). This support group has provided input for the development of laboratory quality systems in Rwanda, Kenya, Botswana, Malawi, Zambia, Uganda, and Tanzania, with approximately 45 centers being supported from the group’s base in Johannesburg. Activities conducted to date have included site assessments, delivery of specific laboratory training programs, design of laboratory space, facilitation of equipment procurement, provision of external quality assurance (EQA) programs, cross-validation studies, method validation, and reviews of relevant standard operating procedures (SOPs). The detailed approach used by the group to set up one or more laboratories is depicted in Figure 1.

ASSAY SELECTION

The repertoire of tests that may be needed in the course of implementing an HIV clinical program can include a combination of the following:

1. HIV diagnosis for infants and adults,
2. Safety testing in the form of chemistry and hematology,
3. CD4 testing for treatment initiation and monitoring,
4. Hepatitis B screening,
5. Viral load testing (considered optional in many programs),
6. Reference testing (e.g., genotyping, which is used for resistance surveillance in developing countries), and
7. Diagnosis of opportunistic infections (with an emphasis on TB diagnosis). 

(Note: A discussion on the development of laboratories for specialized clinical trials, such as vaccine trials, can be found in a 2007 publication by IAVI.)

Ongoing research and development (R&D) needs to be fostered to ensure that laboratory assays to support HIV prevention and treatment initiatives are made affordable and accessible. Such R&D includes novel assay and instrument design, as well as the development of innovative, more affordable diagnostic algorithms and improvements in specimen collection and transport.

SITE NEEDS ASSESSMENT

Site visits are essential to gain an understanding of the region and clinical environment in which the laboratory program will be implemented. At the first visit, the scope of the project is determined (i.e., whether one or more laboratories are needed to serve the needs of a given area). The needs assessment should include a thorough evaluation of population demographics, the local prevalence of HIV and/or other important diseases, and the geography of the local terrain. The political environment, local health-care hierarchy, and mandates of funding agencies also need to be carefully considered. Assessment of the individual laboratory should include a detailed inventory of existing facilities, equipment, technical skills, supplier networks, safety concerns, and waste disposal facilities. Power and

*CLIA guidelines are available at http://www.fda.gov/cdrh/clia.
Figure 1. Proposed approach to the establishment of a new laboratory / laboratory service in African settings
water supplies should also be investigated, since they are frequently erratic in these regions. It is important to assess the current laboratory workload to ensure that any additional sample referral will not overload the existing capacity.

Close consultation with local clinicians is required to determine the repertoire of tests that will be used to support the clinical program. At this stage it is also vital to determine required turnaround times for assays, as this will have an impact on service design. The anticipated rate of patient recruitment into treatment and prevention programs needs to be determined as well, since the workflow design and analyzer selection are entirely related to the volume of tests required. Ongoing laboratory-clinic communication is fundamental to maintaining the overall quality of laboratory services.

**COMMUNICATION STRATEGY**

It is important to establish appropriate lines of communication for the duration of the implementation process; failure to do so early on can derail a project very quickly. Regular communication with the implementing laboratory, whether through face-to-face visits, conference calls or e-mails, should be maintained to ensure the continued momentum of the process. A detailed project implementation plan with defined milestones agreed upon by all stakeholders is also essential to keep everyone’s expectations in alignment. The challenges presented by communication difficulties should not be underestimated, as information technology (IT) infrastructure can be lacking in several areas. Cultural and language differences between local staff and visiting trainers are equally significant and can influence site laboratory staff receptiveness to planning and training activities. For instance, while English is generally accepted as the common language for such activities, the English language competency of the laboratory staff should be assessed prior to the initiation of training.

**BUDGET DEVELOPMENT**

All budgets should be well researched; this may require the assistance of organizations that specialize in project management or local individuals with the appropriate experience. The budget should make allowances for required capital equipment such as analyzers and centrifuges, facility management (e.g., furniture and equipment, facility rentals), staffing costs, ongoing maintenance of major and minor equipment, reagents and consumables, costs of internal and external quality assurance, and courier and sample collection costs. The cost of a test is often calculated based on reagent costs alone. However, all expenses should be taken into account and final test costs per reportable result should be calculated based on cumulative total expenses in order for laboratory servicing to be sustainable. This cumulative total should include the cost of labor for specimen collection, sample analysis, data entry, and reporting. In addition, direct material costs should include reagents, consumables, controls, and calibrators. Fixed costs that are incurred regardless of whether or not a test is processed (e.g., rent, equipment maintenance, quality assurance, and management) should also be factored into the cost per test. A simplified template for test costing is presented in Table 1.

**STAFF RESOURCES**

Professional staff shortages are commonplace in African countries, and skilled laboratory technical personnel are no exception. For instance, the World Health Organization (WHO) has estimated that countries in sub-Saharan Africa would have to increase their workforce by 140% to achieve adequate health coverage. A published survey in Ghana conducted in 205 laboratories revealed that only one-quarter of staff had professional qualifications. Staff turnover rates are often extremely high, with many staff succumbing to HIV infection themselves or leaving the country for better wages
Many of the international guidelines for GLP are intentionally vague and thus not easily translated into practice. Courses need to be designed to focus on basic, practical implementation issues (e.g., implementation of audit trails, development of SoPs, maintenance logs, temperature monitoring, etc.) through the use of working examples. Observations of numerous training courses in the region indicate that many sites are beginning to transfer the skills attained during training to other centers in their region, a very encouraging development. Training of trainers (ToT) workshops may also be useful for the training of senior staff so that they can then conduct their own regional training programs.

The need for laboratory management skills is often overlooked. Once a defined laboratory hierarchy is established, the overall laboratory manager and deputy may need training or refresher courses in laboratory management skills. In addition to all of the principles of GLP, this instruction needs to include practical assistance regarding human resource management, budgeting, procurement, stock control, negotiation skills, and the development of an internal audit process to ensure long-term sustainability of the facility. The identification and appropriate training of a specific quality manager (or individual responsible for quality of testing) and safety officer is of key importance.

Further needs include technical training on how to conduct the assays that have been selected (e.g., serology, CD4 count, hematology, biochemistry, polymerase chain reaction [PCR] for infant diagnosis, and viral load monitoring). After technical proficiency has been established, more advanced training is generally required to ensure that the subtleties involved in monitoring aspects of quality assurance and troubleshooting are understood for each assay. An approach that combines the use of on- and off-site training for each assay works quite well.

Training of clinical personnel at the associated clinical sites should not be overlooked. Topics that may need to be covered include the interpretation of laboratory assays and proper sample collection, particularly if there are specialized requirements such as the collection of dried blood spots for infant diagnosis or plasma for HIV viral load assays requiring specialized centrifugation and transport. If sites are conducting rapid testing, such as HIV diagnosis or B-HCG (beta human chorionic gonadotropin) tests to exclude pregnancy, on-site training is vital, as are mechanisms to ensure the ongoing maintenance of quality and proficiency by clinic staff. This may involve sending a percentage of samples (usually 5% to 10%) to a reference laboratory for confirmatory testing. A regular process in which witness testing of clinic staff is conducted by trained technical staff is also useful to ensure that assays are conducted accurately and safely.

**EQUIPMENT**

Assay and equipment selection is typically determined by the volume of samples to be processed and available budgets. It is advisable to select equipment from a supplier that has a strong local presence and who can guarantee fast turnaround times for servicing, maintenance, and equipment repairs. Feasibility of implementation for any new assay needs to be considered, including (1) the level of technical skill required to conduct the assay; (2) sample collection, transport, and storage needs; (3) the required turnaround time; and (4) workflow and space requirements (particularly for PCR or culture work). Water and power supply for analyzers should be considered very carefully when determining the placement of instrumentation within the laboratory itself. It is prudent to install a generator backup and an uninterrupted power supply (UPS) for all instruments, as electrical power cuts are a common occurrence.

**SPECIFIC ASSAYS**

**HIV Diagnosis**

Most developing countries use rapid HIV tests either singly or in combination for the diagnosis of HIV in adults. These are generally conducted at the clinic as part of a larger voluntary counseling and testing (VCT) process, and their use has facilitated a dramatic increase in access to care in many regions. These assays are by and large easy
to implement; lists of proven and reliable assays are available from WHO and CDC. Limited local validation of new assays is advisable prior to implementation and is of particular relevance in settings where less common HIV subtypes are present. Ongoing surveillance of assay performance is also recommended. Collating data on rapid HIV tests can be challenging due to problematic record keeping in many remote clinics, with few sites having data management systems in place to monitor the number of assays and their performance.

As discussed previously, monitoring of quality is an essential part of any laboratory testing program, and it is advisable that at least 5% of samples are retested in a reference laboratory. This can be easily achieved using dried blood spots to reduce the time needed for sample collection and to avoid sample transport restrictions. A recent study in South Africa evaluating the performance of rapid tests for malaria in the Limpopo province demonstrated the need for improved quality assurance and end-user training. GLP needs to be extended to the clinic operations as well, with factors such as temperature monitoring for kit storage and equipment maintenance factored into daily work practices.

Early infant diagnosis of HIV is particularly complex, since passive transfer of maternal antibodies complicates the use of antibody-based assays. However, recent work has suggested that rapid antibody assays could be used for the screening of HIV exposure in infants, and most groups recognize the need for virological assays for early infant diagnosis. These assays can be in the form of DNA-based PCR assays; quantitative RNA assays; or heat-denatured, ultrasensitive p24 antigen quantitation. It should be noted that nucleic acid–based testing strategies require significant technical skill and dedicated workspace to prevent contamination.

**Hematology**

Hemoglobin is an important independent predictor of outcomes in the setting of HIV. Since many antiretroviral drugs are bone marrow suppressive, ongoing monitoring of hemoglobin is an important component of any treatment program. The selection of hematology equipment is fairly simple and is largely volume driven. In low-volume primary health-care clinics where only a hemoglobin value is requested by clinicians, instrumentation such as the HemoCue system can be easily implemented. As volumes increase and the need for automation arises, there are a variety of analyzers that are suitable for both low- and high-volume ranges.

**Chemistry**

Many HIV-care programs will include a limited repertoire of biochemistry parameters, such as alanine transaminase (ALT) levels. The selection of appropriate analyzers is once again volume driven, but is particularly challenging for the medium-volume, small-repertoire range of instruments. There are sufficient point-of-care (POC) options for low-volume, decentralized testing, as well as high-volume, large-repertoire instruments.

**METHOD VALIDATION**

Method validation is critical prior to implementation of a new method or instrument. A full validation is needed when a new method or instrument is implemented for the first time. However, a full validation process may not be feasible at all sites due to costs or lack of technical or statistical skills. A

---

b For more information, visit http://www.hemocue.com.
partial validation process may be considered when transferring a previously validated method into a new laboratory site. The approach to method comparison can be divided into four distinct phases: (1) obtaining background literature and understanding theoretical principles and performance specifications, (2) design and analysis, (3) compilation of a report, and (4) ongoing monitoring of performance. Several international guidelines and reference documents are available for consultation during the validation process and include the CLIA guidelines (CLIA 88 final rule-2003); NCCLS (now referred to as CLSI [Clinical and Laboratory Standards Institute]) EP9A2, EP5A2, and EP17A4; and the College of American Pathologists (CAP) general checklist. There is much debate as to what constitutes an appropriate method validation process for a new assay or method. This issue has been discussed extensively within organizations such as WHO, CDC, and, more recently, the Forum for Collaborative HIV Research. There is some agreement that the components of an appropriate method-validation process should include the following determinations: (1) precision—within run and between run; (2) accuracy; (3) evaluation of quality controls and reference material; and (4) reportable linear range, linearity, and sensitivity. The validation process should be followed up by a multisite comparison, longitudinal evaluation of patients, and participation in EQA programs to assess ongoing performance.

EXTERNAL QUALITY ASSESSMENT PROGRAMS

Dramatic improvements in overall laboratory performance have been demonstrated in countries or within programs utilizing proficiency testing programs. It has also been established that many EQA programs are too infrequent (i.e., conducted quarterly) to ensure adequate monitoring of performance and that if a problem is identified, testing will continue for several months before a corrective action is implemented. Access to international EQA schemes is limited in Africa, mainly due to the high costs of participation and courier service. Logistical difficulties related to the delivery of EQA samples, including poor courier networks and inefficient customs departments, also make access to EQA challenging. For these reasons, and because of limited resources and fear of reprisal, EQA schemes remain largely underutilized in many African laboratories.

Several EQA programs are, however, available and their selection by a laboratory will depend on the parameters being evaluated, the distribution network of the particular program, the frequency of shipment, and associated costs. The following are well-recognized international providers: CAP (U.S.-based, CLIA certified), United Kingdom National External Quality Assessment Service (UKNEQAS), Royal College of Pathologists of Australasia (RCPA), and Quality Assurance Systems International (QASI). Other programs that are available to assist laboratories within the African region include those provided by WHO, CDC, National Institutes of Health (NIH; offering virology quality assessment [VQA] and immunology quality assessment [IQA]), and the South African NHLS-managed African Regional External Quality Assessment Scheme (AFREQAS). The AFREQAS CD4 proficiency program was initially based on a collaboration between WHO, the NHLS,
and QASI in 2002 for the purposes of establishing monitoring of CD4 testing in the region. The program now runs independently and has facilitated the development of several national EQA programs under the umbrella of the AFREQAS. The program has also been instrumental in facilitating knowledge transfer and providing technical advice and support to ensure that appropriate corrective action is taken when failure occurs in participating laboratories. To date, 35 successful trials have been delivered, with more than 500 sites participating from 20 different countries in the Africa region. Overall performance within the program has been very good, confirming that high standards of laboratory testing can be achieved in many remote African settings.30,31

In the area of HIV diagnostics, HIV serology EQA programs have been extended to include the clinical sites at which the bulk of HIV testing (using rapid tests) takes place. Electronic submission of results has proven to be reliable, ensuring rapid return of results and allowing for immediate corrective action. However, in non-grant-funded sites, communication is often difficult and requires dedicated follow-up and repeated communication by telephone or fax to encourage participants to submit results. Once a relationship is established between the coordinators and participants, compliance for results submission can improve.

LABORATORY SAFETY
Safety issues are generally not given adequate attention in laboratories in Africa, where staff are at great risk of exposure to HIV and hepatitis.32 The working conditions for TB diagnosis are generally substandard in many developing countries and significant resources need to be allocated to ensure that the risk of laboratory-acquired TB is greatly reduced.33 Other serious safety concerns that have been highlighted in the region include lack of access to appropriate waste disposal facilities, such as incinerators, and the absence of provisions for the administration of HIV postexposure prophylaxis (PEP) to staff members.

COURIER AND TRANSPORT SYSTEMS
Transport collection systems in most African countries are generally poorly developed and the absence of transport often severely limits access to testing. This is exacerbated by the requirements of some commonly used HIV diagnostic and monitoring methods, such as viral load and CD4 testing, which require a cold chain or processing within a specified time frame. Some of these issues for CD4 testing have been alleviated through the use of fixatives34 or the development of innovative flow cytometric assay approaches, such as panleucogated CD4 testing, which facilitates delayed testing for up to five days.35,36 The use of dried blood spots37 or other collection devices, such as the SampleTanker, facilitates delayed centralized nucleic acid testing.

CONCLUSION
Experience has shown that even relatively rural laboratory sites can support the implementation of basic antiretroviral programs as long as sufficient investments are made in training and regional support. Willing participation at training courses and high participation rates in EQA programs30 demonstrate that laboratory personnel in the African region recognize the need to attain—and sustain—quality laboratory services. African laboratory professionals have shown that they are willing and able to embrace the latest technologies and apply and or modify them as needed to suit local needs.31 Sustainable laboratory practices based on proven technologies modified to suit local conditions are an essential component of the HIV/AIDS response.

Managing Medicines and Supplies for HIV/AIDS Program Scale-Up

Helena Walkowiak and Douglas Keene

As countries move to rapidly scale up comprehensive HIV/AIDS programs, it is critical that the adequate and continuous availability of diagnostics, medicines, and other pharmaceuticals be ensured at the point of service. If HIV test kits are unavailable, opportunities to offer testing are missed. Stock-outs or irrational use of antiretroviral medicines (ARVs) can result in treatment interruptions that can quickly lead to treatment failure and the development of drug resistance. The success of these programs is also largely dependent on the capability of the health-care team to promote the proper use of ARVs and other products. Inappropriate use can increase the risk of toxicity of HIV/AIDS-related medicines and, in addition, can waste costly laboratory tests and medicines. Despite many improvements, the limited availability of ARVs and HIV test kits continues to be reported as a major constraint to scaling up programs.¹⁻³

A wide range of medicines and other pharmaceutical products are needed to support implementation of a comprehensive package of HIV/AIDS services for treatment, care, and prevention (see Box 1). While a single health facility may not carry all needed products, clients should be able to access products that are unavailable at their local facility through a referral process. Some services require new products, while others need large-scale increases in quantities of existing medicines and supplies. These requirements change as new technologies or formulations become available and as practices or patient needs change. In addition, some products are complex to manage, requiring cool or refrigerated storage and careful tracking of short shelf lives to minimize wastage.

Box 1. Pharmaceuticals Needed to Support Comprehensive HIV/AIDS Programs

- Medicines:
  - Medicines to treat HIV infections (antiretrovirals)
  - Medicines to prevent and treat opportunistic infections (OIs)
  - Medicines for palliative and supportive care
  - Medicines to prevent and treat sexually transmitted infections (STIs)
  - Medicines to treat HIV-related cancers
- Diagnostic test kits for HIV, STIs, and OIs
- Laboratory reagents, supplies, and equipment:
  - To monitor the progression of HIV infection
  - To identify adverse drug reactions
- Medical equipment and supplies
The World Health Organization (WHO) estimates that at the end of 2006, only 28% of people in need of antiretroviral therapy (ART) in all low- and middle-income countries were receiving it and that steep increases in the rate of scale-up will be needed to achieve universal access to treatment by 2010.4 As countries move to decentralize ART services to the primary health-care level, the pharmaceutical management system must meet the challenge of delivering supplies to more service delivery points, across different sectors, and for an increasing number of clients. In many countries, procurement and distribution systems are struggling to keep up with this rapid expansion, and even systems that are working well will be challenged to support the level of scale-up that is to come.4

This chapter provides practical guidance on addressing some of the major challenges related to the management of medicines and other supplies being faced by HIV/AIDS programs in resource-limited settings. Successful approaches and lessons learned for building the capacity of pharmacy and supply services to support scale-up are shared.

APPROACHES TO STRENGTHENING SYSTEMS FOR GOING TO SCALE

As countries plan to scale up their HIV/AIDS programs, a key consideration is whether to integrate the supply of HIV/AIDS-related pharmaceuticals into an existing supply system or, alternatively, to establish one or more vertical or parallel systems. In a vertical supply system, all or some of the functions of the pharmaceutical management cycle (described below) are carried out separately for each program. Limitations to using parallel systems to supply HIV/AIDS programs include the wide range of products needed, the level of expansion to be achieved, and the shortage of skilled pharmaceutical management staff.

In many countries, governments are working with partners to rationalize multiple vertical supply systems and to foster service integration. Most pharmaceutical management systems have some strengths to build upon. A rapid assessment can help clarify what these strengths are and help identify which strategies are needed to build capacity where it is lacking. By prioritizing interventions, facilities can begin implementing new HIV/AIDS programs while working to strengthen existing pharmaceutical management systems for the longer term. Integrating pharmacy and supply services into existing systems allows capacity-building costs to be shared across programs. Integration also ultimately improves pharmaceutical management for other programs, since most improvements are system-based rather than disease-specific. In addition, integrated systems are better equipped to support scale-up, due to the fact that service provision, such as ARV dispensing, does not depend on the availability of a specific member of the pharmacy staff.

THE PHARMACEUTICAL MANAGEMENT SYSTEM

Managing pharmaceuticals in any setting (public or private) and at any level (local or national) follows a well-recognized framework that includes a cycle of selection, procurement, distribution, and use (see Figure 1). Management support functions hold the cycle together, and it is supported by policies, laws and regulations. As problems in any part of the cycle can disrupt the whole pharmaceutical management system, it is important that assessments of existing capacity consider all components of the framework.

SELECTION

The successful scale-up of ART programs depends on good selection practices. Selection involves reviewing HIV-related health problems, developing standard guidelines, and deciding which medicines, diagnostics, and supplies will
Figure 1. Pharmaceutical management framework

be available at each level of the health system. Good selection practices include the rational selection of the most effective and economical treatments or tests for a specific setting, performed through an inclusive and transparent process and underpinned by a plan for implementation. The benefits of standardization for selected testing and treatment protocols include more predictable demand for products, which allows for more accurate quantification; fewer products to procure and store; and lower prices due to bulk purchasing. However, ART selection is complicated by the need for multiple regimens to cover different indications and populations. Lack of clarity about regimen choices and multiple formulation options can confuse prescribers and complicate quantification. Rapidly changing scientific information on effectiveness, adverse effects, or resistance patterns, and the availability of new medicines or formulations, makes it difficult to keep ART guidelines current. However, if guidelines are perceived to be outdated or not based on scientific evidence, prescribers are less likely to follow them.

Points to Remember for a Successful Approach

Comprehensive and detailed guidelines help standardize practices and improve quantification accuracy. Although most countries have developed national guidelines for their HIV/AIDS interventions, program and procurement staff can encounter difficulties in implementing these recommendations. This is particularly true when the clients are children. Programs are better able to quantify needs and standardize procedures for prescribing and dispensing when ART guidelines specify the following:

- First- and second-line regimens, with recommendations for managing toxicity and treatment failure
- Regimens for individuals coinfected with TB and other chronic diseases, as well as for pregnant women and all age groups of children
- Regimens for postexposure prophylaxis (PEP) in both adults and children
- Guidance on managing the ART-experienced patient
- Recommendations for laboratory monitoring
- Recommendations for diagnosis and treatment of opportunistic infections (OIs) for both adults and children
- For children, a range of products to suit all ages, preferred formulations for weight and age, and weight-based dosing recommendations for available products (WHO has developed generic dosing tables for countries to adapt for this purpose.5)

An inclusive and transparent development process facilitates implementation of and adherence to guidelines. The inclusion of service providers and national pharmaceutical management staff in selection committees enables them to contribute to developing guidelines that are easier to put into practice. In addition, participation by representatives of the essential medicines committee can facilitate the addition of products to the lists that guide procurement. Including a wider range of constituencies (organizations or groups) can, in general, help build the credibility and acceptance of guidelines.

Updating guidelines requires planning and adequate budgeting. Regular updates to HIV/AIDS guidelines are necessary but can be costly. The process of planning and securing adequate funding in advance of any changes is very important. For instance, training materials, standard operating procedures (SOPs), supply management forms, and reporting and recording forms may all need to be updated. The launch of the new guidelines also needs to be synchronized with supply management, as it takes time to quantify, procure, and
Data from facilities. Changing needs for ARV regimens as patients experience toxicity or treatment failure can also be hard to forecast. Similarly, estimating requirements for new medicines as guidelines change or new formulations, such as fixed-dose combinations (FDCs), become available can be complex. Further complicating the process are lengthy procurement procedures and long supply pipelines that can delay the introduction of new products.

### Points to Remember for a Successful Approach

A national committee to coordinate procurement and distribution can optimize the purchasing power of multiple partners and improve the efficiency of pharmaceutical management. To improve the coordination of procurement, financing, and distribution activities, some governments have established national-level committees to support HIV/AIDS program expansion. The committee serves as a forum for planning collaborative action to strengthen the pharmaceutical management system. Although procurement managers are responsible for most activities, the committee enables them to work together with policy and program staff to map out current and anticipated service delivery points and targets. This collaborative process should lead to the development of a comprehensive procurement and distribution plan that includes an accurate estimate of resource needs. The committee can also work with the team tasked with quantification to review the quality of data collected and develop assumptions about future needs. It is also crucial that the procurement and distribution plan be updated regularly to ensure that procurement planning, program implementation, and disbursements of funds are synchronized.

Simple tools and training can improve quantification and data collection at the facility level. The provision of simple tools to assist facility-level

---

**PROCUREMENT**

Pharmaceutical procurement consists of quantifying product needs, selecting procurement methods and suppliers, establishing and monitoring contract terms, and ensuring the quality of the medicines and other pharmaceuticals. Quality should never be compromised by pricing concerns or any other factor. In many countries, the complexity of procuring products for HIV/AIDS programs is challenging already weak procurement systems. The increased number of global and local partners, funding sources, and procurement mechanisms has complicated procurement planning, occasionally resulting in duplicative procurements and stock-outs. These complications are compounded by the fact that different funding sources can have different procurement cycles and requirements, resulting in complex record keeping, more orders to generate and track, and multiple brands of the same product.

Quantifying needs for ART programs that are scaling up is particularly challenging. The pace of program expansion often fluctuates over time, and enrollment may periodically slow down when the capacity to deliver services has reached its limit. Staff tasked with quantifying needs at the national level are often handicapped by the lack of reliable data from facilities. Changing needs for ARV regimens as patients experience toxicity or treatment failure can also be hard to forecast. Similarly, estimating requirements for new medicines as guidelines change or new formulations, such as fixed-dose combinations (FDCs), become available can be complex. Further complicating the process are lengthy procurement procedures and long supply pipelines that can delay the introduction of new products.
CASE STUDY 1: THE COORDINATED PROCUREMENT AND DISTRIBUTION SYSTEM FOR ANTIRETROVIRALS IN RWANDA

THE GOVERNMENT OF RWANDA has established the Coordinated Procurement and Distribution System (CPDS) to coordinate ARV procurement and distribution efforts among the government, donors, national institutions, and international organizations. The President’s Emergency Plan for AIDS Relief (PEPFAR), through the U.S. Agency for International Development (USAID), committed funds to the Rational Pharmaceutical Management Plus (RPM Plus) Program to support this coordination process. The CPDS had its beginnings in 2005, when the government coordinated the first national quantification and pooled procurement of ARVs. In 2006, a governance framework that describes CPDS objectives and functioning principles and the roles of its members, developed by consensus with all national and international stakeholders, was approved by the Ministry of Health. The CPDS has two primary components:

- A Resource Management Committee, chaired by the permanent secretary of the Ministry of Health and responsible for political, strategic, and financing decisions
- Technical committees responsible for procurement, quantification, distribution, and monitoring functions

The two components are linked by a coordinator who provides technical advice to the permanent secretary and coordinates the technical committees.

The coordination activities of the CPDS have simplified ART management and lowered costs by harmonizing formulations and brands, reducing wastage, and decreasing the number of purchase orders. Furthermore, to support its coordination efforts, the CPDS has accelerated efforts to strengthen the pharmaceutical sector. Pharmaceutical procedures and tools have been standardized, and pharmacy staff have been trained in pharmaceutical management.

staff in data collection and quantification of ARV and other product needs, coupled with training to improve staff quantification skills, can reduce stock-outs and the need for emergency orders. For district and frontline facilities that are scaling up ART, a modified consumption-based method of quantification is simpler to use than a morbidity-based method. From initial experiences, the consumption-based method appears to be sufficiently accurate, provided that consumption records are reliable, procurement periods do not exceed three months, and the pipeline is full. Data collection tools developed in collaboration with facility staff who actually use the data to quantify needs can improve the quality of the data collected and subsequently submitted to the national level.

Contracts should allow procurement to be flexible and responsive to fluctuations in scaling up. Procurement contracts should include staggered deliveries and allow adjustments to be made
to order quantities in case scale-up goes faster or slower than expected.

**DISTRIBUTION**

Distribution includes clearing customs, stock control, storage management, and delivery to depots and service delivery points. The drive to scale up access to HIV/AIDS programs is exposing weaknesses in the distribution systems of many resource-limited countries. Public-sector supply systems, especially in African countries, are struggling to manage hugely increased volumes of medicines, diagnostics, and other pharmaceuticals. Faith-based and other nongovernmental organizations (NGOs) that supply their own facilities are unlikely, even with expanded capacities, to be able to fill the gap as countries take their programs to scale. Multiple funding streams and parallel procurement systems result in multiple shipments needing to be cleared through customs. In most countries, this is a complex and time-consuming process.

The high value and short shelf life of some HIV/AIDS pharmaceuticals, coupled with frequently changing guidelines and the ongoing introduction of new formulations and technologies, puts pressure on supply managers to keep pipeline stock to a minimum while avoiding stock-outs. This is especially true for ARVs. Because scale-up is unpredictable and patients’ needs can change, interventions such as ART require frequent deliveries to a constantly increasing number of service delivery points.

**Points to Remember for a Successful Approach**

Multifaceted strategies and long-term investments are needed to build the capacity of supply systems for going to scale. Countries are exploring a number of options to strengthen national distribution systems in order to support rapid scale-up, including collaboration with faith-based NGOs and the harnessing of resources within the private sector. Some programs use a combination of distribution mechanisms to increase responsiveness. For example, they may use existing public-sector transport for routine orders and lease private vehicles or use express mail for emergency orders. Additional investments may be needed to improve the security, capacity, and integrity of storage sites at all levels, and to lease or purchase vehicles.

Strengthening inventory management will require resources for training as well as tools to help track commodities and monitor usage at central and site levels. Additional human resource needs may include an individual to coordinate distribution at the national level, and staff time for data collection and supervision. Where systems are integrated, efforts and resources expended to support HIV/AIDS program scale-up can strengthen the supply and distribution of all essential medicines.

Introducing flexibilities to make distribution systems more responsive can help avoid stock-outs, minimize wastage, and facilitate the introduction of new products and formulations. Strategies that can make distribution systems more flexible and responsive to users include increasing the frequency of deliveries, collecting and redistributing excess or short-dated stock, and processing nonroutine orders in a timely manner. Organizing the distribution system so as to limit the number of levels where stock is held can serve to minimize pipeline stock. Such an approach will vary depending on the local context. Some countries have centralized storage at the national level and use a relay system to move supplies to regional and district levels, while others, especially geographically large countries, have decentralized storage to one or more levels in the health-care system. In order to work well, a central management unit should be responsible for coordinating
The availability of pharmaceuticals alone does not ensure access to quality care. Medicines must be properly prescribed and dispensed and clients must use them correctly. For the patient, irrational prescribing and dispensing and poor adherence to ARVs and other anti-infectives can lead to treatment failure and the development of drug resistance. Pharmacy staff play a key role in promoting rational use, and the importance of dispensing activities is frequently underestimated. Very often, pharmacies are understaffed, labels and appropriate packaging are unavailable, and staff lack distribution, communicating with facility staff and program managers to update distribution plans and reallocate supplies based on uptake, and maintaining a robust information system that feeds data on consumption or requirements back to the central unit.

At new sites, allocating “ceilings” for new ART patients can facilitate distribution planning. Allocating monthly targets or ceilings for new patients can assist with distribution planning, especially in the early phases of scale-up, when facilities lack data and experience to calculate requirements accurately.

CASE STUDY 2: STRENGTHENING DISTRIBUTION SYSTEMS TO IMPROVE GEOGRAPHICAL ACCESS TO ANTIRETROVIRALS IN ETHIOPIA

As Ethiopia rolls out ART services, the challenges for distribution include the vast size of the country, the lack of all-weather roads to some facilities, ambient temperatures in certain regions that frequently exceed 30 degrees Celsius, and inadequate storage infrastructure at new sites. To deliver quality ARVs when and where they are needed, the Ministry of Health’s Pharmaceutical Supply and Logistics Department (PSLD) is working closely with PHARMID (the partly government-owned pharmaceutical company) and partners funded by PEPFAR, including the RPM Plus Program, to ensure that efforts are well coordinated. The distribution system for ARVs purchased with grants from the Global Fund to Fight AIDS, Tuberculosis and Malaria (Global Fund) has been integrated with the system used for PEPFAR-funded ARVs to increase efficiency. A distribution plan is developed quarterly; allocations are based on national “road map” targets and adjusted for uptake figures reported by sites. To minimize pipeline stock, ARV medicines are relayed out to PHARMID regional stores and directly on to facilities, which keep just one month of buffer stock. Regional pharmacy staff assist with responding to nonroutine orders and redistributing excess stock. A combination of transport mechanisms, including air, land, and courier services, is used according to the geographical context and the urgency of the order. Facility storage areas are being renovated and staff are being trained on the importance of proper storage of ARVs, including routine temperature monitoring of storage areas.

USE OF PHARMACEUTICALS

The availability of pharmaceuticals alone does not ensure access to quality care. Medicines must be properly prescribed and dispensed and clients must use them correctly. For the patient, irrational prescribing and dispensing and poor adherence to ARVs and other anti-infectives can lead to treatment failure and the development of drug resistance. Pharmacy staff play a key role in promoting rational use, and the importance of dispensing activities is frequently underestimated. Very often, pharmacies are understaffed, labels and appropriate packaging are unavailable, and staff lack...
the basic skills and access to current information necessary to properly counsel patients and advise prescribers.

ART adherence has received much attention, and many clinics and pharmacies collect substantial amounts of data. However, validated measurement tools for monitoring adherence in resource-limited settings are few,\textsuperscript{11} definitions of adherence and defaulting vary, and approaches to improving adherence are not always consistent.\textsuperscript{12} Dispensing medicines for children presents a set of additional challenges. For instance, calculating doses can be complex. Formulations that require the cutting of tablets or the accurate measurement of three different medicines make the delivery of counseling messages to the caregivers of young patients more complex.

**Points to Remember for a Successful Approach**

**Pharmacy staff can play a key role in promoting and monitoring ART adherence.** Studies in the developed world have found that support from pharmacists can positively affect adherence\textsuperscript{13} and that clinical pharmacists appear to have a strong impact on promoting positive clinical outcomes in patients starting ART, particularly in economically disadvantaged areas.\textsuperscript{14} In resource-limited settings, the contributions of traditional pharmacy activities (e.g., checking prescriptions, labeling medicines, and providing medication counseling) in facilitating ART adherence are increasingly being recognized. These responsibilities are also expanding to include adherence monitoring and identification of defaulting patients.

As programs scale up, it becomes more challenging to maintain the quality of pharmaceutical care. Resources can be stretched thin as patient numbers increase and ART dispensing is decentralized to facilities that lack trained pharmacy staff. Delineating health-provider roles in adherence counseling to eliminate unnecessary duplication of efforts can increase efficiency at the pharmacy. Furthermore, validated methods to monitor adherence can enable pharmacy staff to target interventions appropriately. Appropriately adapted SOPs that detail dispensing, adherence counseling, and monitoring processes, and job aids such as medication counseling checklists, can help maintain the quality of pharmacy practices. User-friendly information on ARV medicines, side effects, and interactions can also assist pharmacy staff in communicating key messages to their patients.

**Special efforts should be made to enable pharmacy staff to support ART rollout for children.** Pharmacy staff play an important role in checking ART prescriptions and doses for children, and in providing counseling to their caregivers. When information is lacking or nurse counselors are unavailable, health providers often rely on pharmacy staff to fill the gap. In addition to training in pediatric ART, pharmacy staff may also need to improve their math skills to be able to correctly calculate doses of medicines and quantities to dispense. Information on regimens and dosing recommendations, as well as advice for caregivers on special challenges, should be readily available. In addition, dispensing supplies such as labels, tablet cutters, and measuring devices should be provided. Colored tape can be helpful to distinguish similar-looking bottles of liquid formulations.

**Strengthening dispensing and medication counseling practices for ART programs can improve pharmaceutical care for all patients.** Where ART dispensing is integrated into existing systems and work schedules, staff can often adapt their training in ART medication counseling to improve the quality of counseling for other programs, particularly for patients on chronic treatments, such as for hypertension or diabetes.\textsuperscript{15}
FROM THE GROUND UP: LAYING A STRONG FOUNDATION

The registration process for new products can be lengthy, in some cases taking a year or longer, which can impede the introduction of new HIV/AIDS-related medicines or formulations, such as FDCs for children. The time taken to review dossiers and conduct site visits and the submission of incomplete dossiers by manufacturers may all contribute to these delays.

Points to Remember for a Successful Approach
Fast-track registration and recognition of efficacy and safety evaluations by another medicine regulatory authority can facilitate the introduction of new products.

POLICIES, LAWS, AND REGULATIONS
The pharmaceutical management framework includes all policies, laws, and regulations that impact the availability and use of medicines and other pharmaceuticals. This discussion focuses on one aspect of this framework, pharmaceutical registration. Pharmaceutical registration is the licensing or market authorization of a product based on evidence of efficacy, safety, and quality. The requirements and processes for registering products vary from country to country but will usually involve submission of a scientific dossier and, in some instances, a site visit. In developing countries, previously validated tools, namely, self-report, visual analogue scale, pill identification test, and pill count. The tool was tested at two hospital pharmacies over a 14-month period. The median time of five minutes to administer the tool was deemed acceptable for routine use, and the internal consistency was sufficiently strong to recommend piloting the tool in all provinces. In May 2007, the Comprehensive HIV and AIDS Care, Management and Treatment Plan National-Provincial Working Group agreed to implement the adherence assessment tool in all provinces, and RPM Plus was requested to develop a similar tool for use with children. The intent is to then adapt these tools for other chronic diseases.

CASE STUDY 3: DEVELOPING A TOOL FOR MONITORING ANTIRETROVIRAL THERAPY ADHERENCE IN SOUTH AFRICAN CLINICS

In South Africa, the RPM Plus Program, with funding from USAID, is assisting the national and provincial (Eastern Cape) HIV and AIDS directorates and partners to identify a simple, non-electronic medication adherence assessment tool that can be used by pharmacy staff and other providers at busy ART clinics. An initial literature search revealed that numerous instruments were available; however, no studies described their routine use in resource-limited settings. Given that a 2003 WHO report concluded that no gold standard for measuring adherence existed and recommended a multi-method approach, RPM Plus developed a multi-method adherence assessment tool based on

IN SOUTH AFRICA, THE RPM PLUS Program, with funding from USAID, is assisting the national and provincial (Eastern Cape) HIV and AIDS directorates and partners to identify a simple, non-electronic medication adherence assessment tool that can be used by pharmacy staff and other providers at busy ART clinics. An initial literature search revealed that numerous instruments were available; however, no studies described their routine use in resource-limited settings. of new products for HIV/AIDS programs. Establishing a fast-track mechanism that prioritizes the evaluation and processing of registration applications for specific categories of pharmaceuticals, such as ARVs, is one strategy to expedite registration. Some countries recognize the efficacy and safety evaluations of other medicine regulatory authorities (e.g., countries participating in the International Conference on Harmonization [ICH]) to accelerate the registration process. Strategies to capacitate the regulatory authority to conduct dossier evaluations and manage the workload may include establishing a medicine registration database, staff training, implementing SOPs, and developing a database to manage the dossier review process.

As registration can be one of the longest and most difficult steps in updating guidelines, program managers should begin working with manufacturers early on to initiate the process of registering products.

MANAGEMENT SUPPORT: FINANCING

Funding for HIV/AIDS programs has increased significantly through large-scale initiatives such as the Global Fund, PEPFAR, and other donor initiatives. For many developing countries, achieving the exponential increases needed to take their programs to scale will depend on their success in securing external sources of funding. This funding is crucial not only for procurement, but also for the establishment of efficient pharmaceutical management systems that will function for years to come. The process for developing proposals, costing requirements, and gathering supporting information can be complex; delays in disbursement of Global Fund grants are common and may arise due to difficulties in developing procurement and supply management (PSM) plans, or in getting them approved. As discussed earlier, the large number of pharmaceuticals needed for comprehensive HIV/AIDS programming may require joint planning and budgeting between partners and different government departments.

Points to Remember for a Successful Approach

Developing a multiyear financing strategy as part of an overall HIV/AIDS plan and establishing a mechanism to coordinate proposal development and donor inputs facilitates resource planning. Programs should prepare multiyear forecasts of medicine needs to inform resource mobilization efforts. These forecasts should incorporate product procurement fees and shipping and importing costs into the budget. Financial resources for building the capacity of the pharmaceutical management system at both the facility and national level, including costs for technical assistance, should also be considered. Joint planning and budgeting with other government departments and programs can maximize efficiency in procurement and capacity-building activities. Moreover, donors may be more willing to invest in system strengthening if they know that activities will be cofunded from other sources.

Begin the process of developing PSM plans early to avoid delays in disbursement of Global Fund grants. Difficulties are most often encountered during the collection and verification of data to support the PSM plan, the forecasting of needs, and the development and budgeting of strategies to strengthen pharmaceutical management systems. Requests for technical assistance to help prepare the plan can take time to process. Having a mechanism in place to coordinate procurement, particularly quantification, and capacity-building efforts can facilitate the development of the PSM plan.
Furthermore, a well-functioning PMIS can help managers secure resources for scaling up their programs (see Case Study 4). Building on existing forms, reports, and procedures helps keep costs down and can facilitate acceptance by users. Where multiple supply systems exist with separate information systems, countries will need a strategy for working with stakeholders to standardize data collection tools and reporting requirements to facilitate integration. Improvements to the PMIS are often incremental; transitions are made from manual systems to interim computerized tools to complete software systems as tools become available and patient numbers grow. Changes are made at each step to support new responsibilities or to overcome emerging challenges as programs scale up. Ongoing funding will be needed to develop and maintain the PMIS, and budgets should include costs for printing forms, updating tools, and training, as well as staff time to collect, report, and monitor data quality.

Pharmacy staff need tools, including simple software, to help them collect, analyze, and report data. The data complexity, especially for pediatric ART, the growing number of patients, and the wide range of products can make manual methods of maintaining records and retrieving data more and more difficult to use. As programs outgrow manual tools and pharmacy staff expand pharmaceutical care activities (e.g., adherence monitoring), managers may need to plan and budget for the implementation of user-friendly computerized tools to facilitate record keeping and analysis. Similarly, procurement and distribution staff will need tools to track HIV/AIDS pharmaceuticals by program and funding source as they move through the supply chain. Accuracy in data collection is always a paramount consideration, and poor data-collection practices may not necessarily be improved by computerization. It is important to computerize at appropriate levels to achieve the right mix of

**Points to Remember for a Successful Approach**

A long-term strategy and investment to establish a well-functioning PMIS is essential to support HIV/AIDS programs as they scale up. Efforts to strengthen PMIS systems can take time but ultimately can improve the effectiveness of all pharmaceutical management functions. These benefits can extend to the management of other essential medicines in cases where programs are integrated.
HE FIRST IN-COUNTRY ASSESSMENT by the Global Fund required Swaziland to implement a reliable patient-monitoring and ARV-tracking system before the Global Fund would authorize funds of about US$7 million to purchase ARVs to support expansion of the national HIV/AIDS program. In January 2006, the Ministry of Health and Social Welfare, with assistance from the RPM Plus Program funded by USAID, began strengthening ARV supply management systems at all levels in the country by installing an integrated, computerized pharmaceutical management software—RxSolution—that supports the management of orders, receipts, issues, stocks, and dispensing of medicines at ART facilities.

By the end of July 2006, 11 hospitals and health centers were using RxSolution, and the ordering, inventory management, distribution, and dispensing of ARVs was fully computerized. In addition, system users were generating routine management reports to monitor stock levels and consumption trends, patient loads, and prescribing practices, and submitting them to national- and facility-level managers. By February 2007, no ARV stock-outs had been reported, and in May 2007, the local funding agent recommended that the funding restriction be lifted and that the patient monitoring system be integrated into RxSolution.

computer and manual systems and to provide the necessary training and support.

**MANAGEMENT SUPPORT: MONITORING AND EVALUATION**

Monitoring and evaluation provide the integral link between planning for scale-up and implementation. The challenge for many countries lies in sustaining the quality of pharmacy services as operations expand. With this expansion, managers need to monitor the performance of the pharmaceutical management system without overburdening staff with reporting requirements. Operations research can help identify important lessons on how best to strengthen pharmacy systems for scaling up HIV/AIDS interventions in a way that improves services for all health-care programs. Most importantly, programs are often required to demonstrate results to support new proposals or justify requests for ongoing funding. Pharmacovigilance systems for monitoring adverse events for newly introduced medicines such as ARVs, and for monitoring the quality of products in the marketplace, are commonly weak in developing countries.
Points to Remember for a Successful Approach

Regularly monitoring a few key pharmaceutical management indicators can help managers detect problems early and address them promptly. Pharmacy managers at both central and facility levels should identify a small set of well-defined indicators and ensure that the PMIS routinely collects data to generate and report these indicators. Indicators are useful for evaluating the impact of an intervention designed to address a pharmaceutical management problem and are essential for demonstrating results to donors.

Existing mechanisms for monitoring and evaluation should be used where possible. To minimize the monitoring workload, checklists used for self-monitoring by the pharmacy staff or by supervisors can be adapted to add selected HIV/AIDS program parameters. Similarly, selected HIV/AIDS medicines can be included in the tracer medicine list used by supervisors to track the performance of the essential medicine supply systems. Integrated monitoring systems also enable managers to promptly identify negative effects of HIV/AIDS scale-up on other programs. Efforts to strengthen pharmacovigilance and quality surveillance for HIV/AIDS medicines can be an opportunity to strengthen or develop national systems where none exist.

**MANAGEMENT SUPPORT: ORGANIZING SYSTEMS AND SUPPORTING PHARMACY STAFF FOR GOING TO SCALE**

The benefits of establishing mechanisms at the central level to coordinate procurement and capacity-building activities have been discussed. Likewise, good communication and coordination at the facility level are essential for successful supply management in order to support program introduction and scale-up. Technical and programmatic pharmaceutical management issues will need to be addressed as operations expand. Likewise, the pharmacy will need to set up linkages with other service providers to deliver services effectively, for example, to manage referrals to other departments within the facility or to follow up with patients who are late in collecting their ARV medicines.

The availability of HIV/AIDS-related medicines is dependent upon the leadership, planning, and management capabilities of pharmacy staff as well as their ability to forecast, order, distribute, and monitor pharmaceuticals effectively. However, pharmacists are in short supply in many developing countries, especially in the public sector and rural areas. Other staff must learn new skills and take on new roles where severe shortages of pharmacists exist so that pharmacists can focus on essential oversight activities. Training and retaining pharmacy workers as programs expand to include new interventions and practices is vital for the long-term success of HIV/AIDS initiatives. Training approaches that use one-time intensive sessions to transfer large amounts of information rarely lead to lasting improvements in practice and are even less useful where staff turnover is high.

Points to Remember for a Successful Approach

A facility-level committee, such as an ART team, that plans and reviews progress in scale-up can anticipate pharmaceutical management constraints and address problems promptly as they emerge. The ART team can also help the pharmacy staff quantify needs by identifying potential changes in guidelines or prescribing practices and developing projections for expansion. The role of the various staff in providing medication counseling can also be reviewed to identify gaps in the information being provided to patients and unnecessary duplication of efforts.
CASE STUDY 5: TRANSITIONING THE MANAGEMENT OF ANTIRETROVIRALS AND RELATED PHARMACEUTICALS IN LAOS

The Lao People’s Democratic Republic has been providing services for the diagnosis, care, and treatment of people living with HIV since 2001, with the financial and technical support of Médecins Sans Frontières (MSF). As of September 2007, 663 patients, including 44 children, were receiving ARVs in two outpatient sites.

MSF will continue its support through September 2008, when the Lao Ministry of Health (MOH) will take over responsibility for managing the ART program through the Center for HIV/AIDS/STI, which has to date primarily provided policy and technical guidance. Support for the ART program will be provided through Round 6 funding from the Global Fund.

This transition requires careful planning, since the MOH has not been responsible for the process of quantification, procurement, importation, and distribution of ARVs and other pharmaceuticals, nor the overall management of the program. Furthermore, the provision of medicines in Laos is fragmented, and essential programs are largely donor driven. MSF has implemented manual and electronic systems to track data for patient care and the management of medicines, and supported personnel dedicated to data entry and monitoring and supervision. The MOH plans to expand ART access to five sites within two years, and for three of these sites, implementation of ART will be a new undertaking. MSF has begun planning this transition together with the MOH. It is anticipated that this will be a collaborative process with partners to develop a comprehensive transition plan, evaluate technical assistance needs to support its implementation, and identify human and other resources needed.

Source: Médecins Sans Frontières Switzerland / Laos office and Management Sciences for Health / RPM Plus.

The pharmacy may need to establish linkages for a variety of tasks:
- Managing referrals to and from other facilities
- Following up on patients who are late in collecting ARVs
- Reporting adverse drug reactions
- Providing pharmaceutical support to sites without a pharmacist
- Informing patients about other services at the facility or in the community

Partnerships can enable governments to quickly fill priority vacancies in the public pharmaceutical sector and gradually absorb new personnel. By basing human resource interventions on existing government systems, donors and technical assistance partners can facilitate their eventual integration. In Namibia, PEPFAR committed funds through USAID to support additional pharmacy positions. The Management Sciences RPM Plus Program worked with the Ministry of Health and Social Services to develop a mechanism to hire pharmacists and assistants for priority positions. These positions were aligned with ministry priorities, job descriptions were made commensurate with the public sector, remunerations were set in accordance with government policies, and
ministry staff were involved in selection and supervision. After two years, 18 of 28 pharmacy staff recruited by RPM Plus to support ART scale-up had been absorbed into the government system.21

Pharmacists need training, tools, and a supervisory structure in order to be able to provide technical oversight to facilities without a pharmacist. Pharmacists need good leadership, management, and communication skills to mentor and assist staff to resolve problems and improve services. Support can include assisting staff to quantify needs and calculate storage requirements for program scale-up, implementing SOPs, and assisting teams in conducting rational-medicine-use reviews.

To achieve capacity-building goals for pharmaceutical management, countries need a national training strategy that synchronizes needs for trained pharmacy staff with scale-up goals and incorporates strategies to prepare health-care staff to take on new roles. Performance improvement strategies, such as the monitoring, training, and planning (MTP) approach,22 that empower pharmacy staff to achieve and sustain improvements in the workplace can be an effective alternative to traditional training approaches.

MANAGING REAGENTS, SUPPLIES, AND EQUIPMENT FOR THE LABORATORY: SPECIAL CONSIDERATIONS

In this section, some of the issues that are specific to managing laboratory reagents, supplies, and equipment for HIV/AIDS programs are briefly discussed. Other chapters in this section discuss laboratory diagnostics and patient monitoring at greater length. Interventions to strengthen supply management at the laboratory are usually developed as part of a national laboratory strategy by the ministry of health and national public health laboratory in collaboration with partners, such as the Centers for Disease Control and Prevention (CDC). To be effective, efforts to improve the availability and management of laboratory commodities must complement and support the efforts and inputs of the CDC and other partners who work with governments to build laboratory capacity in developing countries and provide assistance in obtaining equipment, reagents, and other critical supplies. A lack of functioning equipment and interruptions in the supply of laboratory reagents are common to HIV/AIDS programs in many developing countries. Laboratory commodity management systems are invariably weak due to years of underinvestment and neglect. Although funding for reagents, equipment, and supplies has increased substantially in some countries in recent years, laboratory management systems in general will require substantial strengthening in order to leverage and absorb these additional investments. The lack of standardization of laboratory supplies and equipment makes procurement and quantification difficult, and many countries do not yet have a dedicated budget for laboratories. Many laboratory tests are used for other programs in addition to HIV/AIDS, which further complicates quantification and budgeting but does favor integration over parallel supply systems. At the facility level, the pressure of the existing workload is already taxing laboratory staff, equipment, and systems. Laboratory staff typically lack the necessary training, management support, financial allocations, and tools to manage supplies effectively.

Points to Remember for a Successful Approach

Strengthening supply management at the laboratory requires time and a stepwise approach. Laboratory assessments usually reveal numerous commodity management problems and may require some operations to be set up from scratch. Focusing initial activities on the most critical and essential tests needed to support HIV/AIDS
programs, in addition to prioritizing interventions, enables implementers to establish working systems sooner and to gradually expand them to include a wider range of products and services.

Including management staff in commodity management training for laboratory staff enables them to support and ensure efficient use of the laboratory. Strategies to improve the performance of the laboratory commodity management system at the facility level are generally more effective when management and laboratory staff work together to solve problems. This is particularly true for problems related to procurement.

Priority interventions should include strengthening of inventory management at the facility level. Training facility staff in good storage practices and basic inventory management (e.g., introducing stock cards, reorganizing the storeroom, removing obsolete equipment and expired stock) is an essential first step.

A consultative process is needed to standardize laboratory testing requirements for HIV/AIDS programs. The tests and equipment that will be available at each level of health facility should be agreed upon as part of an overall national strategic plan. Although the process can take time, this step is critical to enable procurement staff to quantify needs and develop a procurement and distribution plan. Once agreement is reached, implementation can take time as products work their way through the pipeline. A decision will also need to be made on whether to keep or discard nonstandard equipment currently in use. At the facility level, clinical algorithms for laboratory monitoring should be standardized, and adherence to these standards should be monitored.

Selection and specifications of laboratory equipment should consider the needs of infants and children, where appropriate. For example, laboratory equipment may need to have the capacity to analyze small-volume samples, and CD4 technologies that provide percentage readings may be required.

Where usage data are not available and quantification is based on standard protocols and projected client visits, requirements for quality control, calibration of equipment, training, and wastage will need to be incorporated. If the reagents are used for non-HIV/AIDS purposes, estimates will need to incorporate other uses to avoid stock-outs. Establishing a system to collect consumption data is a priority, particularly at laboratories that serve many sites and a large number of external clients. In such cases, using projected client visits to estimate reagent and supply needs can be especially problematic.
REFERENCES

THIS CHAPTER DESCRIBES THE OVERALL approach to supply chain management for HIV/AIDS commodities in resource-limited settings that was developed by the USAID | DELIVER PROJECT and implemented by John Snow Inc. Since 2000, this approach has been employed in more than 10 countries affected by the HIV pandemic. The challenges and lessons learned in the management of supply chains for HIV/AIDS commodities, as discussed in this chapter, have led to the development of a set of technical strategies and resources that, when tailored to the needs of individual countries and programs, are critical to successful implementation and scale-up of HIV/AIDS programs. The country examples presented in this chapter illustrate specific supply chain interventions that have contributed to strengthening health systems, building human resource capacity, and enhancing the coordination of stakeholder funding, procurement, and technical assistance in supply chain management. These interventions have ultimately resulted in greater reliability and security in the supply of antiretroviral (ARV) drugs, HIV test kits, and HIV-related laboratory commodities for country programs and have helped ensure the continuous availability of these products for the people who need them, when and where they need them.

CHALLENGES IN MANAGING HIV/AIDS SUPPLY CHAINS

While efficient and effective supply chains are needed to support all health service delivery efforts, achieving such supply chains is significantly more challenging and important to consider for HIV/AIDS programs. For example, the success of many HIV/AIDS programs depends on access to the latest HIV/AIDS diagnostic and treatment technologies. As new, more effective and cost-efficient drugs and diagnostics become available, incorporation of these new products into national supply chains can be slowed by bureaucratic registration procedures due to the rigid or cumbersome regulatory environments in many countries.

Supply shortages as a result of budget shortfalls are a common challenge. Budgeting for and procurement of drug commodities in many resource-limited settings are based on available funding rather than on an understanding or rational estimate of actual need. When the supply does not meet the demand, programs are forced to ration the distribution of supplies to the end users—in this
case, people living with HIV and service providers who depend on a reliable supply of medicines, laboratory supplies, and other commodities to maintain their level of health and provide quality services.

Additionally, human resource capacity and skills in supply chain management need strengthening at all levels and across all supply chain functions. Activities critical to a well-functioning supply chain include linking product selection decisions to patient needs and to policies that ensure quality of care, and then reflecting those decisions in the quantification of commodity needs; basing financing and procurement decisions on an established quantification methodology; improving in-country inventory management of HIV/AIDS commodities; and implementing logistics management information systems that inform and drive all supply chain management activities and decisions.

And finally, the fact that procurement planning and procedures are not coordinated with other key supply chain functions, such as financing, quantification, and inventory management, is one of the most common challenges facing HIV/AIDS programs. Coordination efforts are further complicated by the existence of multiple funding sources, procurement mechanisms, and in-country distribution systems.

THE LOGISTICS CYCLE

Logistics refers to the series of activities, resources, people, and information needed to move products through the supply chain to the final customers or end users. The following diagram of the logistics cycle (Figure 1) depicts the key logistics management activities required to operate and maintain a supply chain for health commodities.

As indicated in the diagram, all these activities are interrelated and interdependent. They are all critical for a supply chain to function effectively and efficiently and to be able to ensure an uninterrupted supply of quality products to the end users.

Serving customers is at the top, as customer service is the ultimate goal of the supply chain. For HIV/AIDS programs, the ultimate customer is the person living with or affected by HIV/AIDS.

Based on the ultimate customers’ needs, the next step in the logistics cycle is product selection: choosing which products are appropriate for a service delivery program to meet customers’ needs at a particular point in time. Once the list of products has been determined in compliance with national standard treatment guidelines (STGs), these products should be included on the government’s National Essential Medicines List (NEML) and registered for importation by national drug authorities.

Once specific products have been selected, the next step is quantification of commodity requirements in both the short and the long term. Not only should the quantification include the quantities of commodities needed to serve customers, but it should also include a procurement plan outlining the quantities needed to manage and maintain appropriate stock levels in the country’s supply pipeline.

Based on the quantification of commodity requirements, the financing needed for procurement is determined, funding gaps are identified, and the allocation of available resources or the mobilization of needed resources is undertaken.

After products are procured and shipped, they are cleared through customs and subjected to inspection and quality control checks. Once the products are in the country, inventory management, which includes both transport and storage at perhaps several levels, becomes critical for efficient and effective management of the in-country supply pipeline. Eventually, the products must reach the service delivery point, which might be a fixed health facility, a laboratory, a field-worker’s distribution bag, or a mobile unit.

Finally, the products are dispensed to customers or users, including patients (in the case of ARVs) and laboratory technicians (in the case
of laboratory commodities), and the process repeats itself.

It is important to note that this entire cycle is information driven. Without a functioning logistics management information system (LMIS, depicted at the center of the cycle in Figure 1) to provide data to support decision making for each logistics management activity, the supply chain will not be able to function effectively or efficiently. In addition to an LMIS, other resources, mainly financial and human resources, are needed in order to keep the supply chain functioning.

Finally, quality monitoring mechanisms—of products, services, and system performance—as an overarching activity, must be in place throughout the cycle to track system performance, the impact of interventions, and progress toward the desired outcome of continuous product availability.

Each of these elements will be discussed in greater detail in the sections that follow. In addition, the challenges and lessons learned for each will be described.

**Product Selection**

Product selection is a critical first step in logistics management. The purpose is to select the most effective and cost-efficient commodities to support the goals of the program. When selecting commodities, a number of factors must be taken into consideration, including the following:

- Efficacy and safety
- Product cost and available financing for commodity procurement
- Product storage requirements (such as cold chain), adequate storage space, and conditions to maintain product quality
• Skill level of the personnel using or dispensing the products and any training-related requirements
• Ease of use of the commodity
• Packaging of the products to facilitate distribution
• Shelf life
• Compatibility with existing instrumentation (for lab supplies)

In addition, the product’s registration status with local regulatory bodies needs to be considered. Once registered, selected products must be included in standard treatment protocols and guidelines to ensure their rational use in country programs.

Challenges and Lessons Learned regarding Product Selection

The product selection process can be very complex and time consuming. The following are common challenges and suggested approaches to product selection for ARV drugs, HIV tests, and laboratory supplies.

**ARV Drugs**

The committees involved in updating NEMLS and developing STGs should consult the World Health Organization (WHO) recommendations when selecting ARV treatment regimens that are appropriate for their particular countries as a first step. The WHO publication *Scaling Up ART in Resource-Limited Settings: Treatment Guidelines for a Public Health Approach* provides guidance for countries to facilitate the proper management and scale-up of antiretroviral therapy (ART). In the guidelines, WHO proposes a public health approach geared toward universal access, standardization, and simplification of ARV drug regimens to support implementation of treatment programs in resource-limited settings and to ensure that treatment programs using ARV drugs are based on scientific evidence. The goal is to avoid the use of substandard treatment protocols and to reduce the potential for the emergence of drug-resistant virus strains. In making the product selection decisions, policymakers should also consider key supply chain factors such as formulations, shelf life, cold chain requirements, and packaging, to ensure that commodities can be used successfully at all levels of the health system. The ARV drugs, regimens, formulations, and packaging selected will all affect forecasting, procurement, storage, and distribution.

ART program managers and product selection committees may need to review and update the ARV drugs on a NEML and in STGs frequently to stay in line with the growing body of evidence and experience as treatment is expanded in multiple resource-limited settings. Once updates to STGs and NEMLs have been made, policymakers should consider procurement lead times to ensure the availability of ARV drugs at the time of implementation.

**HIV Tests and Laboratory Commodities**

Deliberate strategies designed to streamline the provision of the many laboratory tests required to support a comprehensive HIV/AIDS program can improve the efficiency, quality, and affordability of testing for the service provider. Test menus, techniques, and equipment used in each country or program are an important consideration when selecting products for procurement. The number of testing platforms used for each test should be reduced in an effort to move toward a laboratory system that makes use of standard equipment across comparable facilities and levels in the health system (i.e., district or regional-level facilities).

Standardization of laboratory procedures and equipment—and thus supplies—can help countries and/or programs better allocate the limited resources available for laboratory services as well as provide the basis for external quality control. Standardization involves defining test menus,
techniques, operating procedures, and equipment for each type of test, for each level of the system, to be applied across all laboratories. The standardization of laboratory procedures and equipment streamlines the quantity and type of laboratory equipment and commodities that are required in countries. Standardization therefore greatly simplifies product selection and allows countries to better allocate limited resources.

Quantification
Once the products have been selected, countries or programs must quantify product needs. Quantification is a critical logistics management activity that links the quantities of product being used and patient needs on the ground to financing and procurement decisions. The quantification results can then be used to better inform manufacturer production decisions.

Quantification relies upon accurate, up-to-date information on
• service provision and consumption/use of commodities,
• stock levels throughout the in-country supply pipeline,
• funding sources and amounts for commodity procurement, and
• national policies and program expansion plans.

Quantification of health commodities involves estimating the quantities and the costs of products required to meet customer demand and maintain adequate stock levels in the supply pipeline. The quantification process takes into account the service delivery capacity, supply pipeline requirements, and resources available for procurement.

Quantification consists of five distinct steps (Figure 2): forecasting product consumption or use; estimating program requirements; calculating the costs for procuring the requirements; adjusting the final quantities to procure according to the amount of funding available (if needed); and developing a supply plan that includes shipment schedules, quantities, funding sources, and suppliers.

Ideally, the quantification exercise should be conducted by a group of key stakeholders including program managers, procurement specialists, and service providers (e.g., pharmacists, clinicians, laboratory technicians) on an annual basis and should be coordinated with government and donor budget cycles. The key benefits of quantification are outlined in Box 1.

The results of quantification may be used to calculate specific order quantities and plan shipment schedules for short-term procurement planning and for medium- to long-term program planning and resource mobilization efforts.

Challenges and Lessons Learned regarding Quantification
The following are lessons learned from DELIVER’s experience in conducting HIV/AIDS quantifications in more than 10 countries. These lessons have since been incorporated into the project’s approach to quantification.

Adequate time, funding, and human resources with appropriate skills to conduct the quantification exercise should be planned and budgeted for. The quantification exercise itself is time and resource intensive. Thus, the success of a quantification exercise is directly related to the extent to which appropriate resources have been deployed to conduct the exercise.

Quantifications should become more evidence-based over time, as the availability and quality of data improve through the strengthening of the LMIS. Data on HIV/AIDS services and product supply are limited and, when available, are often unreliable or insufficient for use in quantifying product requirements. Thus, current quantification exercises are based on informed assumptions as opposed to being based upon past logistics data.
Quantification requires a consultative process with multiple stakeholders and implementers to inform the assumptions about the selection, forecasting, and procurement of HIV/AIDS products. Quantification capacity is limited at the country and program levels, and communication and coordination are typically lacking among key stakeholders and implementers (i.e., policymakers, program managers, service providers, funding sources, procurement agents, and suppliers) on issues related to the selection, forecasting, and procurement of HIV/AIDS commodity needs.

Convening one or more consultative stakeholder meetings throughout the quantification process is recommended to clarify and review the data sources, assumptions, and methodologies used, and to reach consensus on commodity requirements and funding needs. STGs and testing protocols may be inconsistent, may need revision, or may not have been widely disseminated to providers. Consultative stakeholder meetings can be a critical step both toward gaining consensus on guidelines and protocols and toward obtaining buy-in for the results of the quantification process from in-country stakeholders. The meetings
can also serve to facilitate resource mobilization, clarify expectations, and promote collaboration and coordination, especially in the event of disruptions in commodity supply that may affect the availability of products for customers at service delivery points.

The quantification should be based on realistic program plans and on available financing. Program targets may not take into account the service delivery structure’s capacity to increase enrollment of new patients and to continue monitoring existing patients on ART or the supply chain’s capacity to finance, procure, and manage greater volumes of HIV/AIDS commodities. Since multiple sources of funding, procurement mechanisms, and distribution channels are used for HIV/AIDS commodities, quantification and procurement often occur when funding becomes available. This prevents such activities from occurring as part of program planning, when they could be useful for identifying commodity needs and mobilizing resources for procurement in a timely fashion. Performing quantification and procurement only when funding becomes available often leads to stock-outs and expensive emergency procurements.

The results of the quantification should be used to determine specific order quantities and shipment schedules for short-term procurement planning on the basis of available funding. Due to a lack of forecasting data in Zambia, consultation with providers experienced in the provision of first-line ART informed the estimated demand for ART and the breakdown of patients by type of regimen. Because assumptions were informed by providers’ experience, the forecast for first-line ARV drugs was relatively accurate. However, because the program was relatively new, the providers’ experience with second-line treatment was limited. Thus, the assumptions about second-line treatment were less informed by experience and were based largely on expectations, leading to an overestimate in forecasted consumption of second-line ARV drugs. Procurement planning was based on these assumptions—weak as they were—because of the lack of any kind of data. As a result of careful monitoring of consumption, the next second-line drug shipment—scheduled to arrive six months after the quantification and procurement planning exercise—was postponed, thereby preventing a large quantity of expensive second-line ARV drugs from expiring in the warehouse.

The results of the quantification should also be used for medium- and long-term program planning and for resource mobilization for ART. Program managers must prepare medium-term forecasts to be able to coordinate funding and procurement among multiple donors and to ensure uninterrupted supplies of ARV drugs.

The quantification should be reviewed and updated at least every six months, and supply

plans should be adjusted accordingly. Program expansion often does not occur as rapidly as expected. Program targets may not take into account either the service delivery structure’s capacity to increase HIV/AIDS testing and treatment rates or the supply chain’s capacity to finance, procure, and manage greater volumes of HIV/AIDS products. Additionally, program targets for increasing HIV testing may not be linked to program targets for increasing ART patient enrollment.

The emphasis in procurement should be on developing supplier relationships that allow for frequent shipments of relatively small quantities of newly manufactured HIV/AIDS products. When possible, the purchasing contract should allow for accelerating or delaying the delivery of products to the program in response to the actual consumption of those products.

The shipment schedule for all HIV/AIDS products must reflect the lead time and shelf life of each product, as well as the current storage and distribution capacity of the program. For example, products with a short shelf life and cold-chain storage requirements may have to be manufactured and shipped to a country at more frequent intervals than products that have a longer shelf life and can be stored at room temperature. The in-country pipeline for those items would need to be shorter and would need to be delivered to service delivery points more frequently. Products with significantly shorter shelf lives, such as HIV test kits, should be distributed from the central level straight to the service delivery points with no intervening layers of storage, handling, or paperwork. All other technical factors being equal, preference in selection should be given to those products that meet efficacy and safety requirements, do not require cold storage, and have longer shelf lives.

Other lessons learned in quantification specific to laboratory commodities include the following:

- Standard operating procedures (SOPs) for testing services are often lacking. Laboratories tend to individually develop their own SOPs, based on personnel experience, resulting in inconsistent techniques and procedures across laboratories at the same level.
- Testing techniques and laboratory procedures are often dictated by the availability of supplies rather than by standard protocols.
- Implementation of a standard system can pose significant challenges since it requires the training of all laboratory personnel in the recommended testing techniques. As a result, many countries are experiencing situations in which they have functioning machines that are not being used in compliance with the recommended SOPs, again leading to inconsistent use of reagents.
- Program targets may not take into account actual testing capacity and/or supply chain capacity to finance, procure, and manage greater volumes of laboratory supplies.

In the absence of logistics data, the most appropriate methodology for quantifying laboratory supplies seems to be service statistics using the number of each test performed over a period of time (with the exception of general laboratory consumables and durables, which require assumptions on usage data in consultation with laboratory personnel).

Prior to quantifying laboratory supplies, a standardization exercise should be conducted to either develop or confirm and update test menus, techniques, testing procedures, and equipment for each level of the health system. For example, in both Kenya and Uganda, DELIVER was tasked with quantifying laboratory supplies. However, quantification was not possible without first implementing a standardization process for the laboratory system. In each country, stakeholders, in partnership with DELIVER, standardized test menus and techniques; this led to a consensual agreement of
the required reagents and consumables needed for each test and to the subsequent reduction, by roughly 60% to 75%, in the number of different commodities requiring management.3

The standardization process should always be a consultative workshop with representatives from all programs and levels that provide testing services, as well as donors and all key players in the provision of laboratory services. The consultative nature of this process is a critical step toward transferring ownership of the results to in-country stakeholders. These meetings can also help mobilize resources, set expectations, and promote collaboration and coordination, especially if delays in commodity availability occur.

Procurement and Supply Planning
The procurement of HIV/AIDS commodities is a complicated process that varies according to the source of funding for procurement, the recipients, and the regulations that are in place in the host country. The global scale-up of HIV/AIDS treatment and care has increased the availability and accessibility of these services, as well as the required commodities. In many countries, the scale-up has also increased the complexity of the procurement environment and processes due to the increased number of players and steps involved. Thus, it is critical that the procurement process be a well-conceived, transparent process that is both influenced by and accessible to all stakeholders involved in HIV/AIDS commodity procurement.

Supply planning is a critical step in ensuring that products are continuously available in the program. The supply plan provides information on the quantities of drugs to be procured, including their costs and the proposed shipment schedules. This ensures that the commodity stock is managed between the desired inventory control levels. In planning procurement, the program takes into consideration the user requirements as determined during the forecast, the stock on hand in the in-country pipeline, supplier lead times, and the buffer stock needed to ensure an uninterrupted supply in the event of an unexpected increase in demand or shipment delay.

Challenges and Lessons Learned regarding Procurement and Supply Planning
Regardless of how well organized, planned, and managed the procurement process is, unexpected delays are inevitable. The following lessons address specific challenges encountered during the procurement of HIV/AIDS commodities.7

Start the procurement and preprocurement process early so that unexpected delays in the procurement and importation of commodities do not undermine program goals. Each recipient country has unique requirements and regulations and, although general steps in the procurement process may be learned, understood, and improved over time, each country’s procurement process and players are unique. For example, delays can be incurred during a preprocurement step, such as quantification, when a program’s STGs or testing algorithms are in flux or are not finalized; such protocols must be completed before needs can be quantified. Programs that have complete and updated quantifications can engage in procurement planning as soon as funds are available for procurement. Planning should establish a clear timeline for the procurement process up to the date the product is required in-country.

Build flexibility into the supply plan, including the shipment delivery schedules, to minimize product wastage and to ensure that manufacturers can continue to meet global demand. Many HIV/AIDS programs are relatively new or rapidly expanding, which makes forecasts less reliable than for stable programs. To make procurement more reliable, there should be built-in flexibility, such as smaller, more-frequent shipments for
IN 2005 IN NIGERIA, THERE WERE four funding sources for ARVs. Just one funding source, the President’s Emergency Plan for AIDS Relief (PEPFAR), had several implementing organizations, each of which partnered with different organizations that were responsible for different functions of the supply chain. Each funding source had different reporting requirements and different procurement restrictions (e.g., the ability to purchase only from manufacturers that are approved by the U.S. Food and Drug Administration [FDA] or are prequalified by WHO). Procedures for the multiple distribution channels or supply chains were not harmonized, with delivery and pickup systems operating side by side, and different formulas required for calculating orders. Often facilities were receiving commodities from multiple sources. In the case of ARVs, the components of a single regimen came from two different supply chains and were available in multiple brands. Service providers were often required to maintain separate records for each supply chain or implementing agency, and they had to collect some drugs and wait for others to be delivered.

As illustrated in Figure 3, having multiple sources of funding and various agencies involved in HIV/AIDS commodity procurement and program implementation complicates HIV/AIDS service provision, and this complexity ripples throughout the supply chain. This complexity influences the effectiveness of a supply chain in several ways. First, the need for coordination is heightened—from standardizing treatment guidelines to distribution and reporting. In Nigeria, standard treatment guidelines for ART varied by implementing partner. National ARV drug quantification was further complicated by the fact that the drugs included in first- or second-line treatment regimens differed across implementing partners, making it difficult to aggregate requirements. This difference, in turn, complicated the coordination of financing and procurement, because national quantification is critical to ensuring that sufficient funding is available for all patients across implementing agencies, and that procurement plans can be developed to ensure that all the ARVs within a regimen or all the tests within a testing algorithm are available simultaneously.

In response to these challenges, a central coordinating body was proposed at the Federal Ministry of Health (FMoH) to facilitate resource mobilization and coordinate procurement and delivery of HIV/AIDS commodities from multiple partners and sources of supply. This helped ensure a continuous supply of quality HIV/AIDS commodities to the federally supported testing sites.
Figure 3. Funding sources, procurement, and distribution of ARV drugs in Nigeria

products for new programs. Planning for smaller, more-frequent shipments enables programs to avoid bringing in more commodities when programs are overstocked. Conversely, quantities can be added to existing planned shipments to prevent additional costly emergency shipments if product uptake is much higher than expected. However, as programs expand it is important to keep in mind that phasing procurement across several suppliers can add up to several shipments. Therefore, regular monitoring and clear and consistent updates by the procurement agent are critical to enabling programs to stay on track and to navigate the confusion generated by multiple shipments.

**Effective coordination through the sharing of information between partners involved in funding, procuring, and quantifying national needs and/or program needs is essential.** Coordination between in-country partners engaged in separate procurement processes can help ensure product availability and provide flexibility in responding to commodity shortfalls or delays. Effective coordination of all partners involved in procurement or in supply chain management for HIV/AIDS commodities in a country is challenging but can result in significant benefits for the program and for all partners. Many programs receive funding for procurement from multiple sources, and procurement is often conducted through various mechanisms, all of which may have different lead times. Thus, it is important that partners regularly share information on their procurement activities, including quantities of commodities being procured and their delivery schedules. Furthermore, effective coordination among all partners builds a sense of shared responsibility for ensuring continuous product availability and for resolving stock shortages or imbalances when these situations arise.

**Designate a primary contact for each organization or office to ensure clear and streamlined communication.** Developing and maintaining procedures for regular and clear communication among all partners involved in the procurement process can help clarify individual partners’ plans and activities. In order to ensure timely product availability, detailed information on procurement plans must be collected from and shared among all partners involved in the procurement of HIV/AIDS commodities.

This coordination can be achieved by engaging in the following practices:

- Establish clear procedures about regularity and mechanisms of communication.
- Designate individuals to serve as focal points for sharing information and for responding to queries within each organization or office, so that information exchange is not duplicative or contradictory.
- Design standard templates for collecting and sharing information.
- Ensure that all partners are regularly informed about issues that arise, including shipping changes, clearance delays, quality issues, payment requirements, and so on.
- Establish relationships with manufacturers by sharing commodity forecasts in order to minimize global commodity shortages and maximize product availability for recipient countries through strengthened relationships.

**Forecast information is valuable to manufacturers that are experiencing the strain of unpredictable, increasing global demand for HIV/AIDS commodities.** Country- and commodity-specific forecasts enable manufacturers to prepare accurate production projections. Reducing the number of global shortages and product availability crises also benefits recipient countries, donors, and organizations that are committed to ensuring continuous availability of HIV/AIDS commodities.

**Limiting procured items to already-registered products, without exploring options, could**
unnecessarily undermine program goals. Therefore, explore alternative mechanisms for ensuring that unregistered products can be legally imported into recipient countries.

Before a product is eliminated from procurement because of lack of registration, alternatives for obtaining registration should be explored, including mechanisms for fast-tracking registration and for receiving temporary authorization from the national drug regulatory authority of the recipient country to import a nonregistered product. Develop a map of the clearance process to define procedures and assign responsibilities at the country level for all steps in the process.

Defining responsibilities in-country for monitoring shipments, payments, and clearance processes will reduce lead time and potentially lengthy delays, especially if communication procedures are well established. Products can be delayed at numerous points in the process, and understanding the potential obstacles at each stage can help with preventive maintenance. Some obvious but critical steps in obtaining needed information can cause lengthy delays if they are not performed in a timely manner. These include identifying the consignee information and sharing this information with suppliers, determining the length of the customs clearance process, and identifying regulations that govern acceptable remaining shelf lives on imported products. Ensuring that the people responsible for procurement are updated on all issues that arise throughout the process has been a critical factor in resolving bottlenecks. Thus, when follow-up with the procurement agent and manufacturers is required, it can be done instantly.

Developing a stepwise approach to procurement can help multiple partners clearly understand and navigate the process, thereby reducing delays caused by miscommunication. Multiple sources of funding and multiple agencies involved in procurement and implementation complicate management of the program and of HIV/AIDS service provision, and this complexity can carry over into the supply chain. For example, in Nigeria, due to the extensive testing needs of such a large population, there are eight unique funding sources, eight different implementing agencies, and eight different procurement agents involved in the financing, procurement, and distribution of HIV tests. As a result, several different parallel systems have created an environment that, at the national level, makes it extremely difficult for managers to confidently determine whether there are adequate products to meet customers’ needs. Without a clearly defined stepwise approach to procurement, as well as other supply chain functions, the national program is at a heightened risk of delays and stock imbalances due to miscommunication.

Recommendations for Managing HIV/AIDS Supply Chains

A logistics system that manages any health commodity, including ARVs, HIV tests, and laboratory supplies, must have the infrastructure to manage and move commodities to support the supply chain as a whole. The purpose of supply chain management is to ensure a dependable, regular supply of quality commodities at service delivery points.

A well-functioning logistics system is critical to the success of all health programs. Without quality products available for the people who need them, when and where they need them, services cannot be provided.

Specifically, four key supply chain management activities are critical to the success of any supply chain: (1) the inventory control system (ICS), (2) the LMIS, (3) storage, and (4) distribution. These four areas of supply chain management require special consideration when managing ARVs, HIV tests, and HIV-related laboratory reagents and consumables.
While it is highly desirable for all supply systems to be as effective and as efficient as possible, the need for effectiveness and efficiency is even more important when managing ARVs, HIV tests, and laboratory supplies. The specific characteristics of these HIV/AIDS products influence how they are managed and require special adjustments to the supply chain. The particular characteristics of the products and how they are used influence the design of the ICS and LMIS and the storage and distribution networks.

Special characteristics of ARV drugs, HIV tests, and laboratory supplies include the following:\(^\text{10}\):

- Short shelf lives that can range from 6 to 24 months for HIV tests
- High prices, including a significant jump in price when moving from first-line ART to second-line treatment regimens
- Cool storage requirements for some products
- Treatment and testing protocols that require multiple products from multiple sources to be available simultaneously to provide a service
- Dynamic technology for products, leading to constantly evolving treatment and testing protocols
- Higher levels of accountability, including special reporting or other documentation requirements from either donors or manufacturers
- Greater potential for redistribution of products from one facility to another
- Limited number of sites authorized to use the products
- Limited possibility for substitution in the case of stock-outs

**INVENTORY CONTROL SYSTEMS**

Every supply chain must have a clearly defined ICS that informs the commodity manager when to order or issue products and the quantity of products to order or issue, and that helps maintain appropriate stock levels of all products to avoid shortages and oversupplies. The continuous supply of quality ARV drugs and HIV tests can only be guaranteed through the selection, design, and proper implementation of an appropriate ICS.

A number of strategies or ICSs can be adopted to manage commodities of any kind. Some of these, such as a rationing system, are more appropriate in situations in which the products being managed, or the financial resources available to purchase the products being managed, are uncertain. In a traditional rationing system, supplies are allocated based on some set of chosen criteria, for instance, to serve a certain proportion of the poorest clients, to treat a certain proportion of the priority disease burden in the region, or to ensure that a certain product accounts for no more than a certain proportion of the available budget. However, ARV drugs and HIV tests are expected to be in full supply for the desired target number of patients, at least in the short term. To be able to maintain a full supply of products effectively, a maximum-minimum ICS is recommended. Within a maximum-minimum ICS, maximum and minimum inventory levels are set based upon past product consumption. This protects the system from potential stock imbalances by managing the risk of expiries due to overstocks, and by minimizing the need for costly emergency orders due to inadequate stocks. All maximum-minimum ICSs allow resupply decisions based on need and take into account established levels of safety stock; the difference between them determines the point at which an order is placed and which products are ordered.

**Challenges and Lessons Learned regarding ICSs**

The experience of the USAID | DELIVER PROJECT in designing and implementing supply chains for HIV/AIDS and laboratory commodities highlights a few key considerations for ICSs in these contexts.\(^\text{11}\)
Ensure that the length of the supply pipeline accommodates the shelf life of products. The length of the supply pipeline must accommodate the relatively short shelf lives of ARV drugs and HIV tests, which average between 6 and 36 months. Adopting a strategy that affects one element of the supply chain will have an impact on other system elements, and the operation of the supply chain will be adversely affected if any one element is not strong enough to perform under the new requirement. Strategies for minimizing the length of the supply pipeline are listed below and must be selected based on the in-country situation and resources.

- **Utilize as few levels as possible in the supply chain.** This is the single most effective and most common strategy for ensuring relatively shorter in-country pipelines. Although this results in storage and distribution savings, this approach requires more resources for transportation at all levels.

- **Shorten the order interval at one or more levels.** Although this will reduce the pipeline length by reducing the maximum stock level, it will require more frequent reporting and ordering, which may place a burden on service providers to report more frequently and require more frequent transportation (e.g., monthly pickup/delivery instead of quarterly).

- **Reduce the lead time.** Overall pipeline length can be reduced by decreasing the amount of time it takes to fill and process orders and deliver products to the receiving facility. Of course, this increases pressure on personnel and transportation resources. Automation of data collection, reporting, analysis, and order processing can also help to reduce lead times.

- **Maintain lower levels of safety stock.** Safety stock is kept primarily because of uncertainty about the system’s ability to provide routine service. If uncertainty can be reduced—for instance, if suppliers consistently provide timely delivery, if customs clearance formalities are reduced or eliminated, or if communications and transportation within the country are very reliable—the safety stock level can be reduced, along with both minimum and maximum stock levels. However, if the program is rapidly expanding or demand is unpredictable, safety stock should be maintained.

All efforts should be made to reduce the length of the supply pipeline in order to reduce product losses due to expiry. The length of the commodity pipeline (determined by adding the maximum stock levels at all levels of the system) is a key consideration in commodity management. This is especially true for ARVs and HIV tests, as a commodity’s shelf life is often less than 24 months and can be as short as 6 months.

A **forced-ordering maximum-minimum ICS is the most appropriate ICS for HIV/AIDS commodities that require uninterrupted product availability.** In light of the special requirements for ARV drugs and HIV tests, and to take advantage of some of the common characteristics of ART and HIV testing programs, the forced-ordering version of the maximum-minimum ICS has several key benefits. If ordering is linked to reporting, forced ordering will require that all facilities submit a report/order at each order interval, so facilities that are not reporting and/or not ordering can be easily identified. Additionally, any maximum-minimum system allows objective resupply decisions based on need and takes into account established levels of safety stock, with the ultimate goal of having product available each and every time it is needed. Given the lifesaving nature of ART and the public health risks associated with the emergence of ARV drug resistance, uninterrupted product availability must be the primary concern.

Setting a routine reporting period and order cycle for HIV tests, ARV drugs, and laboratory
FROM THE GROUND UP: LAYING A STRONG FOUNDATION

The information is used for calculating resupply quantities to the service delivery points in order to maintain appropriate stock levels. In all programs and for all product categories, logistics managers at all levels need to make routine decisions that affect commodity availability. They need to determine how much of each product to order or resupply, to forecast future demand for a product, and to plan procurements and commodity shipments. They also need to be able to identify potential supply problems at facilities or storage sites or to handle other issues related to commodity management. These decisions must be made using accurate and timely logistics data that are provided by an LMIS. Over the long term, data provided through the LMIS can also help inform policy and product selection decisions.

As discussed above, the LMIS helps logistics personnel collect and manage the information necessary to support sound and objective decision making in managing the supply chain. The goal of this decision making is to ensure an uninterrupted supply of commodities and to identify any problems in the supply pipeline. The LMIS is composed of all the logistics management information systems.

Supplies contributes to effective supply management. During the initial expansion of HIV/AIDS treatment and testing programs, many countries chose to implement a monthly reporting period and order cycle to limit the amount of buffer or safety stock that facilities need to hold and to more frequently to respond to changes in product requirements and adjust procurements. However, as these programs have matured, implementing a bimonthly or even quarterly reporting and ordering period is more sensible, since it relieves the reporting burden on the facility-level staff and the management burden on central-level staff. It can allow central-level staff more time to provide support and supervision to facility staff and to follow up with nonreporting facilities.

LOGISTICS MANAGEMENT INFORMATION SYSTEMS

An LMIS should not be confused with a health management information system (HMIS). The LMIS routinely collects and reports logistics data on commodity use and stock levels from service delivery points to a higher level in the system where specifically, the forms were streamlined to include only information that was being used for logistics decision making, and many of the service statistics, along with other information not directly pertinent to logistics, were removed. After this revision and implementation of the new LMIS, reporting rates from service delivery points rose from 45% to about 80%.

Country example: Logistics management Information Systems

In Zimbabwe, low reporting rates, among other issues, highlighted the need to revise the logistics system, including the logistics management information system (LMIS) tools and processes. In an effort to increase reporting, and thereby provide the central level of the Ministry of Health and Child Welfare with information for decision making, a number of key changes were made to the existing LMIS forms.

Specifically, the forms were streamlined to include only information that was being used for logistics decision making, and many of the service statistics, along with other information not directly pertinent to logistics, were removed. After this revision and implementation of the new LMIS, reporting rates from service delivery points rose from 45% to about 80%.

In an effort to increase reporting, and thereby provide the central level of the Ministry of Health and Child Welfare with information for decision making, a number of key changes were made to the existing LMIS forms.
forms and documentation used to maintain records and produce reports on the logistics system.

An effective LMIS provides regular and timely information to decision makers. Information is used to make short-term resupply decisions and long-term procurement and program management decisions. The need for timely and accurate commodity data increases when there is a rapidly expanding program, as is the case for HIV/AIDS programs, where demand for services and client uptake is highly unpredictable.

**Challenges and Lessons Learned regarding LMISs**

**Link routine reporting to commodity ordering.** There are many benefits to linking routine reports to commodity orders. For example, a system with monthly reporting and monthly ordering has inherent advantages over a system with monthly reporting and quarterly ordering. Often, commodity managers may ignore reporting that does not produce a tangible benefit or result. A tangible result in this case would be defined as receiving commodities as a result of an order linked to a report.

**Data that do not have direct benefit to the management of commodities should not be collected, in order to avoid overburdening the LMIS.** Depending on the needs of the particular program’s existing information systems and the logistics system design, data that are not required for logistics purposes may be included in the LMIS for HIV/AIDS commodities. The LMIS may be required to capture additional types of data, such as service statistics and epidemiological data, which are often needed by different program managers. These types of data can ultimately assist in making logistics-related decisions, such as forecasting. However, reporting formats should not collect any data that do not benefit commodities management. For example, in Zimbabwe, low reporting rates fueled the need to revise the logistics system, including the LMIS tools and processes. In an effort to increase reporting, and thereby provide the central level of the Ministry of Health and Child Welfare with information for decision making, a number of key changes were made to the existing LMIS forms. Specifically, the forms were streamlined to include only information that was being used for logistics decision making, and many of the service statistics, along with other information not directly pertinent to logistics, were removed.

**Always collect and report consumption data for ARV drugs and HIV tests; do not use issues data as a proxy.** While the use of issues data as a proxy for dispensed-to-user or usage data may be acceptable in general essential-medicines programs, the level of rigor and accountability required in ART programs makes this practice unacceptable for HIV/AIDS commodity management. In addition, concerns regarding the security of ARV drugs, HIV tests, and laboratory commodities from a therapeutic, safety, and financial perspective impose greater demands for accountability.

**Refrain from altering the content and formatting of the LMIS to accommodate the funding mechanism.** The landscape of supply chain management for ARVs and HIV tests is marked by the presence of multiple donors operating with different agendas, program objectives and goals, and reporting requirements. Due to these often competing agendas, there may be pressure to determine the contents or data items included on the LMIS according to the requirements of the funding mechanism. However, while funding mechanisms constantly change, typically the logistics data needed to run a system do not change significantly over time. Therefore, data collected on the LMIS forms should suit the particular program needs and be used for decision making; they should not be dictated by individual donor requirements. If funding-mechanism
reporting requirements are so specific as to require additional data or information, then those data or that information should be collected and reported separately, not within the LMIS used for commodity management.

**Lessons specific to ARV drugs include the following**:10
- The patient data that are collected and reported should be limited to the number of new and existing patients by treatment regimen—data that can be used for routine logistics decision making.
- If a system captures estimates of new patients, provide worksheets to translate patient numbers into the product numbers required for commodity management.
- Select and consistently use one unit for recording consumption and stock on hand of ARV drugs (e.g., tablet, capsule, or mL per bottle for liquid formulations).
- Clinical or programmatic information used for program monitoring should be collected separately from logistics data and patient data collected for logistics decisions.

**Lessons specific to HIV tests include the following**:
- To assist in decision making, track usage of HIV tests by purpose of use, brand, and use of test.
- Use the individual test as the unit for recording all HIV-test-related logistics data.
- Manage test-related supplies through the existing system for laboratory supplies.

**Lessons specific to laboratory supplies include the following**:
- Use issues of stock as consumption data. Use and maintain stock-keeping records. Given the difficulty of tracking actual consumption of laboratory commodities, issues from stock at the lowest level—usually within the laboratory itself—should be used as a proxy for consumption. Include commodities used for quality assurance and quality control, as well as wastage in issues when recording issues data.
- Use the unit of issue as the unit for stock-keeping and reporting. The unit of stock-keeping should be the packaging unit of the commodity as received from the source of supply. Examples include a 500 g bottle, a box of 100 slides, and a kit containing 100 tests. If a stain is distributed in 25 g bottles, the unit of stock-keeping is one 25 g bottle. Although actual consumption data will not be collected on most laboratory commodities, a few commodities, known as tracer laboratory commodities, should be tracked by actual usage with an activity register.
- Routinely report stock levels, issues, losses and adjustments, and stock-outs. If using a pull (requisition) system, link reporting with reordering.
- Use an activity register to track the actual consumption of a small number of tracer commodities.

**STORAGE AND DISTRIBUTION**

The purpose of a storage and distribution system is to ensure the physical integrity and safety of products and their packaging as they move from the central storage facility to service delivery points and into the hands of the clients/patients. A sound storage and distribution system will help ensure that products reach the client in usable condition, with minimal loss or waste.

Proper storage procedures help ensure that storage facilities issue only quality products and that there is little or no waste due to damaged or expired products. When all levels of the pipeline follow appropriate storage and distribution procedures, clients can be assured that they have received a quality product.
Acceptable storage facilities (e.g., warehouses, storage rooms) are clean and secure, and adequate distribution systems have dependable and secure delivery vehicles. It is desirable for the pipeline to be as short as possible. In the context of storage and distribution, a shorter pipeline can have a positive influence on the security and quality of the products being distributed. Having fewer levels in a system means fewer storage points and fewer instances of transporting products. Limiting the number of times products are transported reduces opportunities for product damage to occur. There are also fewer people handling the products, which can help to increase accountability and minimize loss, damage, and pilferage.

**Challenges and Lessons Learned regarding Storage and Distribution**

When feasible, the storage and distribution of HIV/AIDS commodities should be integrated into an existing system. Integrating the storage and distribution of HIV/AIDS commodities can help avoid the duplication of activities and result in better use of limited resources. However, it is critical to ensure that integrating these products into an existing system also makes sense from the perspective of overall program and product management concerns. The feasibility of operating a fully integrated system will depend on a number of factors, including the management and reporting structure, the number of facilities involved, and the available resources.

Provide greater security for the storage of HIV/AIDS commodities. Due to the high value of HIV/AIDS commodities, higher levels of security are required for these commodities. Storage facilities should include a locked storage area within the warehouse or storeroom, providing limited access to HIV/AIDS commodities; higher levels of accountability should be required, and more frequent audits performed.

Ensure increased security of HIV/AIDS commodities during transport. Transport should provide the same level of security for the product as the storage facility does. Vehicles used to transport high-value commodities must be secure, with an enclosed bed and locking doors. For personal security, drivers should be equipped with radios and be in frequent communication with their dispatchers while on delivery.

First-to-expire, first-out (FEFO) inventory management procedures should be used in order to limit losses incurred due to product expiry. Because of the short shelf life and high cost of HIV/AIDS commodities, special care must be taken to follow FEFO stock management. Product expiration dates should be monitored to ensure that products are used before expiration to reduce waste. In addition, commodity managers must take action immediately if there is a risk that products will expire before they can be used. Action may include returning the products to the supplying facility for redistribution or directly transferring the products to a facility that can use them before they expire and notifying the procurement and program management units of such actions.

When reissuing returned drugs, special attention should be given to ensure the maintenance of product integrity. In HIV/AIDS programs, excess supplies may be returned to issuing facilities. Although guidelines regarding product contamination must be respected, in some programs these products may be reissued for use by other patients or clients. If reissuing occurs, these products must first be inspected. If the product’s packaging shows no signs of tampering or damage, and if the product is not close to expiry, it can be reissued for further use.

HIV/AIDS commodities should be delivered to accredited sites only. Commodities should be distributed only to sites that are accredited or otherwise authorized to use them. This is easy to control in a vertical system; only authorized sites will
be submitting orders for those products. In an integrated system, an extra level of control or oversight may be required. This may mean separate order forms for HIV/AIDS commodities, which are submitted only by accredited facilities, or it may mean an extra signature by program personnel authorizing the order to be filled. Keep in mind that there should not be so many controls in place (e.g., extra signatures) that movement of the commodities is delayed.

Consider using private or other courier/express mail facilities. Depending on the number of sites to which commodities are being delivered and other available resources, it can be advantageous to use local courier or express mail (post office, DHL) services to distribute HIV/AIDS commodities. If the number of sites is extremely limited, it may be much less expensive to distribute products through these channels rather than maintaining one or more vehicles and the personnel needed to operate them. However, keep in mind that couriers must also be able to maintain product safety and follow security guidelines, including cool storage for those products that require it.

Ensure that products used together are distributed together. Some HIV tests come packaged with most, if not all, of the consumable supplies needed to run the tests. However, several available tests do not come equipped with the necessary supplies. ARV drugs must be used in certain combinations in a specific regimen. If one drug is missing from a regimen, no substitutions can be made, and the patient cannot be treated. In both cases, all necessary products are ideally ordered together to provide the services the customers need. It is essential that the entire complement of products ordered is distributed together, at the same time, so that services such as HIV tests and ART can be given immediately upon receipt. If a reliable supply chain already exists for laboratory consumables, including those used with HIV tests, then that supply chain can be used to order and distribute lab supplies. It is then the job of the service provider to ensure that all necessary supplies are available where and when services are provided.

ARV drug prescribing and dispensing practices and HIV testing practices should be standardized. Nonstandardized practices cause distorted consumption patterns and stock imbalances, resulting in an inability to accurately assess the stock status (months of stock on hand) of HIV/AIDS commodities for the national program. Therefore, national programs should standardize practices. For example, new programs should institute monthly prescribing and dispensing practices to allow for close monitoring of consumption and stock on hand of each ARV drug. This will help minimize stock imbalances and prevent stock-outs.

CONCLUSION

HIV/AIDS commodities pose many unique challenges to supply chain managers. In order to overcome these challenges, supply chain management activities must be executed in a coordinated and deliberate manner that is continuously linked to procurement. Creating and maintaining this link will lead to more efficient and effective supply chains, resulting in increased product availability at all levels of the health system.

The essence of the quantification process is to ensure that there is continuous availability of commodities within the system. This process should be broad based and should include inputs from all stakeholders involved in the supply and management of these commodities.

The context within which HIV/AIDS programs are implemented is constantly changing, requiring an agile supply chain that can respond to this dynamic environment. However, it is important to note that all supply chain interventions must also be implemented within the prevailing regulatory
environment. National policies and procedures must be used to inform procurement and supply chain management decisions in order to ensure continuous product availability.

It is also important to clearly define and harmonize all policies and procedures related to each supply chain, such as ART guidelines, prescribing and dispensing protocols, HIV testing protocols, and laboratory testing menus that outline specific tests and techniques at each level. These policies and procedures will effectively simplify supply chain interventions.

Finally, critical to the success of any HIV/AIDS program is the coordination and collaboration among all stakeholders involved in the procurement process, whether procurement is conducted through a single channel or multiple channels. Coordination of stakeholder inputs and activities can greatly enhance the effectiveness and efficiency of the supply chains for HIV/AIDS commodities.
REFERENCE LIST

The clinical course of HIV infection is characterized by active replication of HIV during periods of clinical latency, with resulting depletion of CD4 T lymphocytes. The rate of CD4 depletion is highly variable between individuals. Progression from initial HIV infection to AIDS can occur within months to years, and median survival ranges from approximately 8 to 12.5 years in the absence of treatment, with older age at seroconversion and higher HIV RNA levels within 12-36 months of seroconversion both associated with rate of disease progression.1-3

Current treatment guidelines recommend the initiation of combination antiretroviral therapy (ART) based on clinical status with incorporation of CD4 data where available.4,5 CD4 count and pretreatment HIV RNA levels have been correlated with risk for progression to AIDS.6 CD4 T-lymphocyte counts and HIV RNA levels once ART is initiated are associated with response to treatment7 and risk of disease and death.6 HIV RNA following ART is a surrogate marker of virologic response that has been used in clinical trials, in observational studies, and to license new therapeutic agents. Randomized clinical trials have employed outcomes including the maintenance of HIV RNA levels below 50 copies/mL or 400 copies/mL, although there is little clinical evidence of a difference in the threshold value used to assess virologic suppression. A retrospective analysis by Powderly et al, however, showed increased durability of sustained virologic response to treatment among individuals attaining HIV RNA levels below 50 copies/mL compared to nadir HIV RNA levels between 50 and 400 copies/mL, with time to virologic suppression also found to be a key prognostic factor in the durability of virologic response to treatment.9

The cost of CD4 cell count and HIV RNA testing has been a deterrent to the widespread availability of these technologies in resource-limited settings. CD4 cell enumeration is more widely available than HIV RNA testing. CD4 cell responses, however, do not necessarily correlate with HIV RNA responses to treatment. Discordant responses in CD4 cell count and HIV RNA levels during ART occur in a substantial proportion of subjects. Discordant responses include virologic response after 16-24 weeks that does not meet the currently recommended levels of <400 copies/mL using a standard HIV RNA assay or <50 copies/mL using a sensitive HIV RNA assay,
accompanied with a substantial rise in CD4 cells. Alternatively, individuals with virologic suppression to <400 or <50 copies/mL may not demonstrate an increase in CD4 cell counts. The impact of discordance in HIV RNA and CD4 cell count responses during ART was evaluated by Moore et al. Those with a concordant virologic response to <500 copies/mL and a gain of >50 CD4 cells per mm$^3$ within a median of six months of starting ART had the lowest hazard of death, and a progressively increasing hazard of death was identified among those with virologic suppression without a gain in CD4 cells, individuals with a gain in CD4 cells without virologic suppression, and—the highest hazard—those with persistent viremia and no gain in CD4 cells.

Use of a combination of CD4 counts and HIV RNA testing in the management of ART provides higher prognostic estimation of the risk of disease progression than does the use of either test alone. Viremia >1,000 copies/mL despite ART is strongly associated with increased risk of progression to AIDS among individuals whose initial CD4 lymphocyte count was >250/mm$^3$. Conflicting data exist on the importance of low-level viremia and emergence of drug resistance, with some studies demonstrating continued immunologic benefit without significant emergence of drug resistance, while other studies suggest continued evolution of drug resistance with low-level viremia.

With the advent of lower-cost alternatives, the possibility of implementing CD4 count and HIV RNA testing in the management of ART in resource-limited settings is increasing. CD4 counts are measured using fresh blood samples, while HIV quantitation and drug resistance testing can be performed on plasma stored at -70$^\circ$ C to optimally preserve viral RNA. Methods to circumvent the need for refrigeration include the use of dried blood/plasma spots, which increases the capacity for storage and transportation of samples to centralized laboratories for HIV RNA and drug resistance testing. In this chapter, we will review the various methodologies available and affordable assays in development that may be used to quantify CD4 T lymphocytes and HIV RNA, and discuss methods used to identify HIV drug resistance.

**CD4 T LYMPHOCYTE ENUMERATION**

Peripheral blood mononuclear cells (PBMCs) express unique proteins on the cell surface, often associated with immune function. Cells with different immune functions express different surface molecules. These surface proteins are designated “CD” (for “cluster of differentiation”) and are followed by a numerical designation. Over 300 CD molecules have been described.

All PBMCs display CD45 on their surface, albeit in varying concentrations—with more monocytes than granulocytes and more lymphocytes than monocytes. Monoclonal antibodies to the CD45 surface protein can therefore be used to separate PBMCs from other blood cells. T lymphocytes express different cell-surface CD proteins; while both helper and cytotoxic T lymphocytes express CD3 surface protein, helper T cells express CD4 surface protein and cytotoxic T cells express CD8 surface protein. Even though CD4 T cells comprise only about 0.1% of the cells in peripheral blood, these cells play a pivotal role in the immunology of HIV, since the death of this cell type leads to severe immunodeficiency.

Since a decrease in CD4 T cells is associated with increased risk for opportunistic infections, disease progression, and mortality, CD4 T-cell count monitoring has become the gold standard for determining prognosis and staging for eligibility for ART and antimicrobial prophylaxis against opportunistic infections. Moreover, recent studies have indicated that CD4 enumeration is a cost-effective intervention when compared to clinical monitoring alone in resource-limited settings.
There are multiple types of technologies for CD4 T-cell enumeration. Ultimately, the goal of CD4 T-cell monitoring is the determination of the absolute numbers (per μL of blood) and the percentage of CD4 T cells. In addition, CD4 T lymphocytes as a percentage of total lymphocytes is used for pediatric monitoring. Technologies for CD4 enumeration must, therefore, differentiate PBMCs from red blood cells (RBCs), lymphocytes from PBMCs, T lymphocytes from B lymphocytes, and CD4 T lymphocytes from CD8 T lymphocytes.

The technology selected for CD4 cell monitoring is best chosen based on the nature of the laboratory service being delivered. So, in advance of obtaining these technologies, a careful assessment of specific local demand for testing and laboratory capacity should be undertaken. For instance, will there be a requirement for absolute CD4 counts (adults) and/or CD4 counts as a percentage of total lymphocytes (children)? Will there be a low, medium, or high volume of patient samples? What are the projected changes in sample volume? Is an adequate supply of trained laboratory staff readily available to meet the volume demands? What are the funding limitations? Thus, it is imperative that when selecting a particular CD4 enumeration technology, the present needs of the laboratory and the requirements forecast for future expansions be considered. Methods for CD4 enumeration range from manual procedures to high-throughput systems. One size does not fit all, so the particular methods and materials chosen for CD4 enumeration should reflect the clinical demand, laboratory capacity, and budget.

**Fluorescence-Activated Cell Sorting**

*Conventional Flow Cytometry*

Globally, BD FACS Calibur, Coulter Epics XL, Coulter FC 500, Partec CyFlow SL, and Apogee A40 account for most of the conventional systems in use today for the enumeration of CD4 cells. These systems measure cells in flow. Fluorescence-activated cell sorting (FACS) simultaneously measures multiple physical characteristics of cell flux in a fluid stream through a beam of light. Fluorescence intensity, via fluorescent antibodies coating cell-surface proteins, provides an effective method for cell sorting and the enumeration of CD4 T lymphocytes.

The fluorescence-activated cell sorter is a machine that can rapidly separate the cells in a suspension on the basis of size and the fluorescence color. Briefly, a cell suspension containing cells labeled with a fluorescent dye is directed into a thin stream so that all the cells pass in single file. The dye is coupled to a monoclonal antibody and binds to those cells coated with the antigen for which the antibody is specific. This stream emerges from a nozzle vibrating at some 40,000 cycles per second, which breaks the stream into 40,000 discrete droplets each second. Some of these may contain a cell. A laser beam is directed at the stream just before it breaks up into droplets. As each labeled cell passes through the beam, its resulting fluorescence is detected by a photocell. If the signals from the two detectors meet either of the criteria set for fluorescence and size, an electrical charge (+ or -) is given to the stream. The droplets retain this charge as they pass between a pair of charged metal plates. Positively charged drops are attracted to the negatively charged plate and vice versa. Uncharged droplets (those that contain no cell or a cell that fails to meet the desired criteria of fluorescence and size) pass straight into a third container and are later discarded (Figure 1). This apparatus can sort as many as 300,000 cells per minute. The cells are not damaged by the process. In fact, because the machine can be set to ignore droplets containing dead cells, the percentage of viable cells among the sorted cells can be higher than that in the original suspension.19,20
**Optics:** Lasers, lenses, and filters illuminate cells and cause excitation of fluorescent molecules, signals that can be captured for analysis. As particles pass through the laser, light is scattered and the tagged surface molecules fluoresce. Lenses collect scattered and fluorescent light. Optical mirrors and filters route specified wavelengths of light to detectors.

---

**Figure 1. Schematic representation of FACS analysis**

*Components of FACS: fluidics, optics, electronics*

The components of the FACS machine work together to determine how cells scatter laser light and emit fluorescence as the cells pass through the laser.

**Fluidics:** Fluid dynamics create a stream of liquid containing cells, spaced to pass through the laser beam one at a time. The laser beam path intercepts this line of cells.
Laboratory and pharmacy services...
training for a laboratory technician to achieve proficiency. When beads are required for calibration and to convert from a dual to a single platform, the cost of running the assay can be doubled.

Pan-leukogating (PLG) is a method for CD4 enumeration developed in South Africa. The method has been validated repeatedly.21 PLG uses specific flow cytometry labeling and gating strategies that analyze the side scatter of CD45 fluorescence and CD4 fluorescence to identify cells of interest. It is able to determine total lymphocytes and the CD4 percentage of total lymphocytes for pediatrics. Since the side scatter of CD45 and CD4 do not change significantly within a five-day period, the use of PLG has the advantage that cells may be batched and the analysis performed later in the workweek. PLG is generally used as a dual platform (the technician would need to add calibration beads to use PLG as a single platform, however, which would significantly increase the cost of the test).

**Dedicated Flow Cytometry**

Dedicated flow cytometry systems (e.g., BD FACSCount, Partec CyFlow Counter, PointCARE AuRICA) use a known concentration of whole blood (50 μL) in a tube containing the monoclonal fluorochrome-conjugated antibodies anti-CD3, anti-CD4, and anti-CD8. The monoclonal antibodies are conjugated to yellow or red fluorescent dye. A fixed number of fluorochrome-labeled polystyrene reference beads are also present in the sample tube. Labeled cells are treated with a fixative and then placed into the flow cytometer. In the flow cytometer, the labeled cells pass through a green laser beam in single file. This causes the cells and beads to fluoresce. Computer software sets a “threshold” for separate groups of cells. Only signals with intensity greater than the set threshold value will be processed. This allows signals from nontargeted cell groups and cell debris to be filtered out. The method excludes most erythrocytes, platelets, monocytes, and granulocytes. CD3 lymphocytes and reference beads appear above the set threshold. Software automatically sets fluorescence gates around groups of cells. An elliptical region (gate) is set around each cell population. The machine optimizes the position of the gate based on the cluster center, and cells are counted within the gated region.

The gate defines the numerical or graphical boundary of the targeted cell population. Different cell-surface markers and/or degrees of light scatter can be used to define cell populations. Gated cells are divided further into T cells and non-T cells based on staining and the fluorescence of the CD3 monoclonal antibody. Staining of the gated T-cell population for surface expression of CD4 or CD8 is performed using a monoclonal antibody for each CD4 and CD8 T cell, measured in separate tubes (one tube uses CD3/CD4 and the other uses a CD3/CD8 combination). The machine software counts and analyzes the cells in the appropriate gate. The instrument prints the results, which include the absolute numbers of CD4 (positive for both CD4 and CD3), CD8, and CD3 T lymphocytes; the CD4-to-CD8 lymphocyte ratio is also provided.

Two of the more commonly used dedicated instruments, the FACSCount (BD) and the CyFlow Counter (Partec), have several important differences. These single-platform technologies use either calibration beads (FACSCount) or volumetric sampling (CyFlow Counter) in place of the hematology analyzer used in dual-platform systems. In the FACSCount, reference beads are used to measure volume indirectly; one disadvantage of this technique is that the use of beads adds considerable cost to the assay. Volumetric sampling does not use reference beads and therefore is significantly less expensive. In addition, unlike the FACSCount, the CyFlow Counter allows the use of bottled water in place of sheath fluid, which not only substantially decreases the cost of the assay but also decreases the amount of waste generated.
Advantages of the dedicated systems include that they are less expensive than other flow cytometers and they fully automate the calculation of total cell counts (FACSCunt and AuRICA). They lead to less human error because operator-specific interventions are minimized. These are single-platform machines that do not require separate hematology equipment. RBC lysis may not be required, decreasing the time and cost involved (FACSCunt and CyFlow Counter). In addition, external quality assurance (EQA) programs are available to ensure ongoing accuracy. A CyFlow Counter can be powered by a 12-volt battery and AuRICA reagents do not require refrigeration. Disadvantages include the fact that dedicated systems are for adult monitoring only (FACSCunt and CyFlow Counter), because although CD4 T lymphocytes can be enumerated, these machines do not determine total lymphocyte counts. These are closed systems that use the manufacturer’s reagents, and the reagents can be relatively expensive. Importantly, these systems can be used only for CD4 enumeration and cannot be expanded to other types of assays. Moreover, there is a requirement for some computer software literacy on the part of the operator (e.g., CyFlow Counter). Incorrect reading of the sample fluid level can be a source of error. Special care must be given to distinguish CD4 lymphocytes from CD4 monocytes (CyFlow Counter, AuRICA).33-32

**Microcapillary Flow Cytometry**

Microcapillary flow cytometry technology (Easy CD4/CD8, Guava Technologies) is a relatively recent addition to the world of flow cytometry and differs from conventional methods in that it does not utilize sheath fluid to move the cell suspension. Instead, cells are adjusted in suspension to enable them to pass in a known concentration through a microcapillary filament that permits contact with the laser one cell at a time. The concentration is determined by the volume of the sample and the volume of reagents added. It uses CD3 for T-cell gating. Alternatively, CD2 + CD19 for lymphocyte gating can be used. CD2 surface protein is present on T cells and natural killer (NK) cells, and CD19 surface protein is present on B cells; T + B + NK cells = total lymphocytes. CD2 and CD19 are linked to a single fluorochrome, so if either cell-surface marker is present the cell will fluoresce the same color. Thus, since the microcapillary system is able to enumerate total lymphocytes, the CD4 count as a percentage of total lymphocytes can also be determined, allowing this method to be used for both pediatric and adult monitoring.

Microcapillary flow cytometry has several advantages: it requires only 5-10 μL of blood/sampling; the system requires minimal training, in contrast to conventional FACS; and no sheath fluid is required, which decreases cost and biohazardous waste. In addition, it is an open platform and therefore can use reagents from other manufacturers. The reagents cost relatively less than those for the other systems. Daily control is inexpensive (US$0.60/day). Since it is not a dedicated system, the instrument can potentially be used for other assays besides CD4 monitoring. Minimal daily maintenance is required, and the instrument is easy to operate. Reagents are heat stable (refrigeration is recommended, however) and can perform well when stored for up to one month at 37° C. The disadvantages of microcapillary flow cytometry include a requirement for computer literacy and knowledge of the principles of flow cytometry. The assay is operator dependent, since the operator controls gating. Also, there is a requirement for RBC lysis, which increases the processing time per sample.33-36

**Manual Methods for CD4 Enumeration**

Dynabeads and cytospheres are inert latex spheres—“beads”—that are coated with a murine monoclonal antibody. Whereas Dynabead assays use magnetic beads, cytosphere assays do not. Both of these
manual assays are highly labor intensive. Appropriate training and quality control are required to minimize operator variability and ensure confidence in the validity of the results. The advantages of manual methods are that they require simple technology with minimal equipment beyond a low-cost microscope; they can be performed at remote sites, they are useful for laboratories with few samples, there is no need to buy a flow cytometer, and costs are significantly reduced because there is no need to repair and maintain expensive instruments. The disadvantages of manual methods are that they can only be used for adult monitoring (since these methods cannot calculate the CD4 percentages of total lymphocyte counts), they have low throughput (approximately 10 samples per day), they are labor intensive (approximately 10 minutes per sample), and subjectivity is introduced since cells are counted visually. Furthermore, manual methods are impractical in large cities with large numbers of samples to be tested. Samples with higher cell counts are prone to inaccuracy due to overlying nuclei, and the absence of standardized practices for EQA may limit confidence in results. In addition, the hemacytometer is fragile and can break easily, samples must be processed within six hours, and it is difficult to differentiate monocytes from lymphocytes (cytospin assay).

**Future Technology: Microfluidics and Cell Affinity Chromatography**

Microfluidics and cell affinity chromatography is a promising technology that is currently in development and has recently been validated. The microchip device is a self-contained system that uses a direct volumetric method and requires no labels, beads, or other reagents and can thus greatly reduce the cost and complexity of CD4 enumeration. Only a small sample volume (10 µL) is necessary; an assay could be performed with a finger-prick sample of blood, avoiding venipuncture and minimizing medical waste. These advantages would make the assay feasible in remote settings with limited laboratory infrastructure and would greatly expand the types of health facilities at which CD4 cell testing could occur.

The key elements of the approach include a microfluidic channel with immobilized monoclonal antibodies for affinity isolation of CD4 cells from unprocessed whole blood, microliter volumes of sample and wash buffer, and efficient CD4 T-cell capture with minimal contamination by blood monocytes. CD4 cell counts are obtained by enumerating all cells isolated from a 10 µL volume of blood, using an inverted light microscope. The assay is rapid and requires only 10 minutes from blood collection to cell count. In its current format, only two simple accessories, a pump and a basic light microscope, are required for the entire assay. At high and low CD4 counts there may be cross-contamination by monocytes, giving falsely decreased CD4 counts. Clearly a promising technology, the microchip will need to be tested under field conditions before it can be routinely implemented in resource-limited settings.

**QUALITY CONTROL**

All systems require calibration and the use of control samples. These samples are produced by individual instrument manufacturers. Calibration samples are used to set instrument parameters. Control samples are used to test assay performance. These controls may be obtained through preserved blood samples or normal donor samples. Calibration samples and control samples must be processed daily to ensure the correct performance of the instruments and reagents used for patient testing. Many laboratories do not perform internal quality assurance (IQA), however, due to the associated cost; calibration samples can be rather expensive, and processing control samples requires the use of antibody reagents.
Internal Quality Assurance
Fluorochrome-labeled beads within test kits should be analyzed at recommended intervals. Control beads may be used to test the performance of various instruments, for example, the FACSCount Control Kit uses beads at known concentrations (zero, low, medium, high) to test the linearity of the system and to compare its results to known results for calibrators, which are used to ensure that machines are calibrated and functioning adequately.

External Quality Assurance
A particular challenge for ART roll-out programs in resource-limited settings is the need for EQA. If EQA is not performed consistently, the inaccuracies of an instrument may not be detected and may create errors in the results of CD4 enumeration. Several international EQA programs exist. Canada's International Program for Quality Assessment and Standardization for Immunological Measures (QASI) is the most attractive program, as the Canadian government is currently subsidizing the program to help reduce costs. Other programs include the United Kingdom's National External Quality Assessment Scheme (UK-NEQAS) and the U.S. National Institutes of Health's VERIQAS.

The EQA program sends the laboratory a preserved blood sample with a known number of CD4 T lymphocytes. The clinical laboratory runs the sample and sends the results back to the EQA site, which in turn analyzes the results and sends a report back to the clinical laboratory. Access to the EQA programs is platform independent, so everyone has access to the programs, regardless of product, if desired.

Several issues related to optimizing EQA must be addressed, however. How can EQA samples be sent across borders into other countries? How can the EQA test results be sent back to the program for analysis? How can the analysis be sent back to the country performing the test? The costs involved in processing the EQA samples—the costs of reagents used to process samples, shipping costs, and the tariffs and duties levied on entry to each country—are also an issue. A possible solution could be for individual countries to develop EQA programs of their own. This would solve the problem of sample transfer across borders and would reduce costs, as international shipping costs could be eliminated and it would be less expensive to pay for EQA analysis inside the country than to pay for analysis in the United States, the UK, or Canada. This approach would require a regulatory organization inside the country to certify standards, monitor the process, and report results, however.

The clinical laboratory decision to perform EQA is generally based on cost and is not universally mandated. Therefore, EQA performed at a frequency well below what is recommended by the instrument or test manufacturer, especially in remote areas, may compromise the reliability of laboratory testing services.

HIV-1 RNA Quantitation
Methods for HIV quantitation rely on the ability to detect HIV-derived nucleic acids, RNA or DNA. This can be achieved through direct amplification of HIV-derived nucleic acids or though amplification of a signal that is designed to detect the HIV target nucleic acid. The tests vary in terms of (1) the volume of patient sample required for testing, (2) the amount of time and labor required for testing, (3) the risk of contamination during the testing procedure, (4) cost, and (5) the lower limit of detection of HIV-1 RNA. Three quality-controlled commercial assays have been widely available for the quantitation of HIV-1 in plasma for over 10 years. The Amplicor HIV-1 Monitor Test (Roche Molecular Systems) relies on reverse transcription (RT) and polymerase chain reaction (PCR) amplification.
to quantify HIV-1 RNA levels. The nucleic acid sequence-based amplification (NASBA) system (Organon Teknika) employs an isothermal target nucleic amplification method in which relative quantities of amplified sample and internal control RNA are detected by hybridization with a labeled probe to quantify sample HIV-1 RNA levels. The branched DNA Quantiplex HIV-1 RNA assay (Chiron Corporation, now Bayer) uses hybridization and amplification of the RNA-probe signal as a means to quantify RNA levels. HIV RNA quantitation using these three methods generates comparable results within 0.5 log₁₀ copies/mL. Disadvantages of these systems include the large volume of plasma (2 mL) required by the Quantiplex HIV-1 RNA assay and the NASBA assay's labor-intensive RNA extraction, with a higher risk of sample contamination. The Amplicor assay requires 0.5 mL of plasma and has a built-in mechanism to prevent contamination; the most recent version (version 1.5) has been modified to allow quantitation of different subtypes of HIV-1 with better accuracy than prior versions, which underestimated HIV RNA levels, particularly in subtypes A and E. At present, the most commonly used HIV-1 RNA quantification method is RT-PCR amplification of plasma using the Amplicor HIV-1 Monitor Test, version 1.5. This method allows for varying sensitivity: the standard procedure has a lower limit of detection of 400 copies/mL, achieved by the extraction of HIV-1 RNA from a fixed volume of plasma, while the ultrasensitive procedure has a lower limit of detection of 50 copies/mL, achieved by high-speed centrifugation to concentrate virus particles prior to lysis.

Efforts to develop less costly tools to measure HIV RNA in resource-limited settings have led to the adaptation of several techniques. One of these techniques uses real-time RT-PCR to quantify HIV RNA. In this method, RNA is reverse transcribed into complementary DNA (cDNA), and PCR amplification is performed using primers targeted at conserved regions of HIV-1. A fluorescent reporter probe with an adjacent quencher is included in the reaction during amplification. The quencher probe absorbs the fluorescence from the reporter until successful PCR amplification of the target region of cDNA releases the fluorescent reporter probe away from the quencher. Separation of the reporter probe from the quencher results in measurable fluorescence emission by the reporter probe. There is a linear relationship between the amplification and hence fluorescence detected, and the quantity of cDNA and hence viral RNA in the sample. Serial dilutions of standard samples with known quantities of HIV produce a standard curve with the HIV-1 RNA copy number (log₁₀) plotted against the cycle threshold (CT), the number of PCR amplification cycles required to reach the same point of exponential amplification within the group of standards and samples being tested. The HIV-1 RNA content of the samples is then determined by plotting the CT of the sample against the standard curve generated using the standard samples with known quantities of virus.

Various groups have investigated the use of real-time RT-PCR for HIV-1 RNA level monitoring, and two real-time PCR HIV quantitation systems received approval from the U.S. Food and Drug Administration (FDA) in 2007. One of these, the COBAS AmpliPrep / COBAS TaqMan HIV-1 Test (Roche), can quantitate 48-10,000,000 copies/mL of HIV-1 with an accuracy of ± 0.3 log₁₀ copies/mL. The standard curve generated in this system uses the same quantitation standard that is incorporated into the Amplicor HIV assay. Comparable HIV-1 quantitation is achieved relative to the Amplicor HIV assay, and the assay can be used for HIV-1 group M subtypes A through H. The Abbott RealTime HIV-1 Assay (Abbott Molecular Inc.) is another real-time PCR assay for HIV-1 quantitation that has
recently received FDA approval. This assay is able to quantify 40-10,000,000 copies/mL of HIV-1 RNA. The limit of detection varies based on the volume of plasma used: use of 1 mL of plasma results in a lower limit of detection of 40 copies/mL, 0.5 mL in a lower limit of detection of 75 copies/mL, and 0.2 mL in a lower limit of detection of 150 copies/mL. HIV-1 group M and O subtypes are quantifiable using this method, within 0.3 \log_{10} copies/mL. The standard used in this assay is a viral standard from the Virology Quality Assurance (VQA) Laboratory established by the AIDS Clinical Trials Group, as well as the World Health Organization’s first international standard for HIV RNA (97/656). The Nuclisens EasyQ HIV-1 version 1.1 assay is a real-time quantitation assay that is available in Europe. This assay incorporates the NASBA target amplification with real-time detection using a molecular-beacon system. An internal RNA calibrator is added to each sample prior to RNA extraction and amplification to allow quantitation of HIV-1 in the sample. Results obtained by this method are comparable to the results of the Roche Amplicor Monitor HIV-1 ultrasensitive assay.50

Another method that has recently been explored as an alternative to HIV RNA quantitation is an RT assay (ExaVir Load Quantitative HIV-RT kit, Cavidi Tech AB). This method uses HIV RT from the lysed virus isolated from patient samples to create DNA-RNA hybrids during an overnight incubation. The quantity of DNA-RNA hybrids created is measured by colorimetric readings at baseline, two hours into incubation, and at the end of the overnight incubation. Viral RT activity is expressed as femtograms per milliliter, and dUTP values are converted to generate an estimate of copies/mL. Initial evaluation of this assay by Greengrass et al found that measurement of RT activity was not affected by concomitant administration of an efavirenz-containing antiretroviral regimen.51 Sivapalasingam et al investigated this method in samples infected with subtype B HIV-1 in the United States, as well as in patient samples from Cameroon where the predominant subtype is CRF02_AG; the correlation between RT activity and HIV-1 RNA level varied between the subtypes, with \( r=0.898 \) for subtype B HIV-1 samples, and \( r=0.669 \) for CRF02_AG HIV-1 samples. Stevens et al evaluated this method using subtype C HIV-1 infected patient samples, and found that there was no change in RT activity until the HIV-1 RNA level exceeded 3.5 \log_{10} copies (3,000 copies/mL), with increased variance seen with rising HIV-1 RNA levels.53 This RT assay is labor intensive but has potential application as a phenotypic assay for drug resistance and may be considered an additional tool in centralized laboratory settings.

HIV-1 DRUG RESISTANCE TESTING

HIV-1 drug resistance is defined as continued viral replication despite ongoing antiretroviral treatment, resulting in plasma HIV-1 RNA levels above a clinically relevant threshold due to the loss of the viral suppressive effect of antiretroviral medications. Testing for drug resistance is performed using one of two methods, genotypic or phenotypic assays. Genotypic assays identify amino acid changes in the viral genome that have been shown to correlate with clinical failure or diminished in vitro susceptibility to specific antiretroviral medications. Phenotypic assays test the activity of the reverse transcriptase or protease gene product to determine the concentration of drug required to suppress viral replication, measured as the IC50, relative to a wild-type reference strain of HIV with no drug resistance. Lack of inhibition of viral replication by addition of a specific concentration of an antiretroviral agent in a phenotypic assay is described as a fold change relative to a wild-type virus.

Population-based sequencing is the primary method used for genotypic drug resistance testing. Genotypic assays using population-based
sequencing determine the predominant nucleotide at each position along the segment of genome targeted by the antiretroviral agents in question. There are currently two FDA-approved laboratory systems to perform genotypic sequence testing to detect mutations that can arise during the use of protease and reverse transcriptase inhibitors: the TRUGENE HIV-1 Genotyping Kit and the OpenGene DNA Sequencing System (Visible Genetics Inc. / Bayer Inc.) and the ViroSeq HIV-1 Genotyping System (Celera Diagnostics / Abbott Laboratories). Both of these genotype sequencing methods are FDA approved for use with subtype B HIV-1. The ViroSeq HIV-1 Genotyping System provides all the reagents required for RNA isolation, RT, and PCR amplification of the entire protease region and amino acids 1-335 of reverse transcriptase. The recommended analyte is 0.5 mL of plasma or serum with >2,000 copies/mL of HIV-1 RNA. The reagents for dideoxynucleotide dye-terminator sequencing are included, but final sequencing requires a separate Applied Biosystems genetic analyzer or sequencer. The ViroSeq HIV-1 genotyping system software allows sequence assembly and editing of generated sequences. The recommended analyte for the TRUGENE HIV-1 genotyping assay is plasma containing >1,000 copies/mL of HIV-1 RNA. As reagents for RNA extraction are not included in the assay, RNA extraction can be achieved using any of a number of RNA extraction methods. The TRUGENE HIV-1 genotyping assay contains the reagents needed to perform RT, PCR amplification, and cross-linking and immunoprecipitation (CLIP) sequencing reactions, an alternative dye-terminator reaction to sequence the entire protease region and amino acids 40-247 of reverse transcriptase. CLIP of the amplified product is followed by the generation of sequences using the Visible Genetics Clipper sequencer, and sequence analysis using the accompanying OpenGene system software. Both assays produce a drug resistance report indicating the amino acid positions at which the viral population contains a mutation, and studies have shown that both the ViroSeq and TRUGENE HIV-1 genotyping assays are more than 98% accurate for base calling.54,55

Many groups use alternate genotype resistance tests using “home-brew” RT, amplification, and dideoxynucleotide sequencing. However, these home-brew methods may not have undergone rigorous analysis to determine the assay sensitivity, specificity, and reproducibility. The generated consensus sequence data are compared to a reference wild-type strain to determine the presence of mutations that have been associated with drug resistance on the basis of clinical outcomes or in vitro testing. Interpretation systems such as those incorporated into the Stanford HIV drug resistance database (http://hivdb.stanford.edu) or the Los Alamos HIV database (http://hiv-web.lanl.gov) are then used to determine the susceptibility of the predominant viral population to available antiretroviral agents.

Mutations that confer drug resistance result in a change in the structure or activity of the enzyme targeted by the antiretroviral drug.56 The nomenclature used to describe the mutation lists the amino acid found in the wild-type virus followed by the amino acid position followed by the mutant amino acid; for example, K103N denotes the change from an arginine to a serine at amino acid position 103 of the reverse transcriptase, this being the signature mutation associated with non-nucleoside reverse transcriptase inhibitor (NNRTI) drug resistance. Distinct drug resistance patterns are seen for some of the antiretroviral medications. While a single point mutation may confer drug resistance to some agents, such as NNRTIs or lamivudine (3TC), drug resistance to other antiretrovirals requires
the accumulation of multiple mutations before viral suppression is impaired. For example, drugs such as zidovudine and stavudine may result in a series of mutations known as thymidine analog mutations (TAMs), which cumulatively confer resistance to those drugs. An extensive analysis performed by Kantor et al evaluated the relationship between HIV-1 main group subtypes, treatment, and drug-resistance-associated mutations. The authors found that mutations that developed in the treatment setting in non-B subtypes were similar to those in subtype B HIV-1, the predominant virus in Western Europe and the United States. However, important differences in drug resistance resulting from use of various drug combinations may emerge as access to treatment and monitoring increases among individuals with non-B HIV-1 subtypes.

Population-based genotypic sequencing only identifies drug-resistant variants present in 20%–30% of the viral population, depending on the interpretation of chromatograms. There is considerable variation in the accuracy of the detection of mixtures at resistance codons by population sequencing. It is, therefore, possible that drug-resistant mutations are present below the threshold of detection by population-based techniques, and even a 20%–30% mixture may elude detection. This is particularly true where there has been poor adherence or if an individual has interrupted his or her ART. This can result in a false-negative drug-resistance assay from plasma RNA, as the wild-type virus may rapidly overgrow mutant viruses with a reduction in drug exposure. Reinitiation of treatment in an individual based on the results of a population sequence performed during treatment interruption may thus provide a false assurance of susceptibility.

There are now more sophisticated methods that allow detection of minority variants that may harbor drug-resistance-associated mutations, also known as minority quasispecies. Methods to detect and quantify minority quasispecies with drug resistance include single genome sequencing (SGS), allele-specific PCR, an oligonucleotide ligation assay (OLA), a LigAmp assay, clonal analysis, and heteroduplex analysis. These technologies are able to detect drug resistance mutations that exist below the limit of detection by population sequencing. Clonal analysis allows for ligation of a single copy of genetic material, a bacterial vector, which is then grown in culture. Plasmid DNA isolated from each bacterial colony representing a single quasispecies is sequenced. Analysis of the sequence of plasmid DNA from multiple colonies (clonal isolates) provides a representation of the viral quasispecies within the host HIV-1 RNA population. Clonal analysis is labor intensive and expensive; it is typically used primarily for research purposes rather than surveillance or patient care. SGS is also expensive and labor intensive, and, because it requires multiple clean rooms to avoid contamination, it is limited to major research centers. Multiple dilutions of cDNA are PCR amplified to identify the reaction well that contains a single copy of the viral genome. To obtain a repertoire of viruses that are thought to represent the quasispecies within an individual, sequencing is then performed on amplicons from multiple wells assumed to contain a single viral genome. Application of this technique among a group of individuals with viremia despite combination ART showed the presence of multiple drug-resistance-associated mutations below the level of detection of population-based genotypic analysis.

Technologies to detect point mutations, such as real-time PCR, OLA, and LigAmp, are relatively cost-effective, but the test must be performed separately for drug resistance at each specific amino acid position being examined. Techniques that can identify the K103N mutation at levels of 1 copy
per 1,000 viruses were able to identify persistent K103N in the majority of patients who failed NNRTI therapy, which is suggestive of the clinical importance of some of these minority drug-resistant variants. The first version of the OLA was not robust in detecting mutations in subtype C HIV-1 and was modified to improve its performance. The LigAmp assay involves ligation of mutation-specific oligonucleotides to amplified DNA and detection of the bound oligonucleotide by real-time PCR, which permits the differentiation of wild-type from mutant viruses within a viral population. This method has been applied to test for residual drug resistance to NNRTIs following the administration of single-dose nevirapine for the prevention of mother-to-child transmission of HIV, though the clinical implication of persistent low-level NNRTI resistance in this setting has not yet been defined.

Most of these sophisticated tools will likely be used in central, more technically advanced laboratories, given the instruments required to perform these tests. However, their availability will allow for public health surveillance monitoring for drug resistance as access to treatment continues to increase.

Expanding the Role of Pharmacy Staff in Antiretroviral Therapy

Helena Walkowiak and Douglas Keene

Rational Pharmaceutical Management Plus (RPM Plus) Program, Management Sciences for Health, United States

The pharmacy department has a pivotal role to play in the provision of quality antiretroviral therapy (ART) care, through both ensuring an efficient supply of medicines and delivering patient-oriented services to promote appropriate use. Studies in the developed world have found that support from pharmacists can positively affect adherence and that clinical pharmacists appear to have a strong impact on promoting positive clinical outcomes in patients starting ART, particularly in economically disadvantaged areas. In many developing countries, initiatives to scale up ART have focused attention on the pharmacy and on making better use of pharmacists, whose skills and training are often underutilized. Currently, the role of the pharmacist and other pharmacy staff in supporting the ART program varies considerably between and within countries as managers explore different models of service provision and pharmacists embrace the opportunity to expand their role in ART care.

Pharmacy practice takes place at different levels: the system (national, provincial, or district), the facility (including the health-care team), supply management, the individual patient, and the community level. Substantial gaps exist in the scope and performance of pharmacy practice at all levels in most resource-limited settings. The introduction of an ART program can serve as an entry point to strengthening practices and expanding patient care activities at the pharmacy to benefit all health-care programs. The ART program is refocusing attention on the importance of traditional pharmacy activities, such as dispensing, including checking prescriptions, labeling medicines, and medication counseling. Increasingly, pharmacy responsibilities are expanding to include a wider range of patient care activities, specifically adherence monitoring, medication-related problem monitoring, and identifying and following up on defaulting patients. Supporting nonmedical staff and community caregivers in the distribution and appropriate use of medicines is another important undertaking.

Estimates of the number of pharmacy staff needed to support ART scale-up range from less than one to three staff per 1,000 patients, depending on how responsibilities for dispensing and especially counseling are allocated between cadres. In one study, Kenya was estimated to need a 50% increase from 2005 levels in the number of public sector pharmacy “specialists” to meet the U.S. President’s Emergency Plan for AIDS Relief target of supporting 250,000 ART patients by 2008. However, many countries,
especially in sub-Saharan Africa, have a severe shortage of pharmacists. Ethiopia, Mozambique, Rwanda, Tanzania, and Uganda have three or fewer pharmacists per 100,000 people, compared with the United States, which has 88 pharmacists per 100,000. Migration of pharmacists overseas is a major cause of shortages in many resource-limited countries. In Ghana, almost two-thirds of the 140 pharmacy school graduates migrated out of the country in 2003. Furthermore, pharmacists tend to be concentrated in the private sector and in urban areas. For example, in Uganda, 90% of the pharmacist workforce is located in just one of four regions of the country. Given the inadequate supply of pharmacists to support scale-up and the move to decentralize ART services to the primary health-care level, where pharmacists are few, the role of the pharmacist in ART needs to be redefined and reoriented to maximize the efficient use of the most skilled cadre of staff. In addition to pharmacists, other pharmaceutical service staff may include pharmacy technologists, technicians, or assistants; nursing staff; and other health-care workers who have been given responsibilities for dispensing or managing medicines. These other cadres of workers must learn new skills and take on new roles, thereby releasing pharmacists to focus on more specialized functions and supportive supervision.

This chapter highlights experiences in expanding the role of pharmacists and other pharmacy staff to support the introduction and scale-up of ART in developing countries.

**SUPPORTING ART INTRODUCTION AND SCALE-UP AT THE SYSTEM LEVEL**

At the national, provincial, or district level, the pharmacists and other health workers of the ministry of health responsible for managing pharmaceuticals make important contributions to planning and managing the introduction and scale-up of ART, including developing enabling legislation, regulations, and policies. In several countries, the national-level staff responsible for pharmaceutical services work closely with the national AIDS control committee and donors to coordinate ART procurement, financing, and distribution (see chapter in this section entitled “Managing Medicines and Supplies for HIV/AIDS Program Scale-Up”). Pharmaceutical management staff also work increasingly with other government departments and programs to maximize efficiency in capacity-building activities. Other important functions include contributing to proposal development and, particularly, to developing the procurement and supply management plan for applications to the Global Fund to Fight AIDS, Tuberculosis and Malaria. Other evolving roles for national-level pharmacy staff that can serve as a starting point for strengthening good pharmacy practices for all health programs include the development of pharmacy practice standards for facilities dispensing antiretroviral drugs (ARVs), national standard operating procedures (SOPs) for ART pharmacy services, and accreditation guidelines and audit tools.

Involving pharmacists responsible for implementing ART at the national and local levels in ART medicine selection committees enables them to contribute to developing treatment guidelines that are easier to put into practice. A number of countries have identified pharmacists to work with the national, provincial, and, in some cases, district AIDS control teams to tackle ART-related pharmaceutical issues and to support sites in introducing and scaling up ART services. Given the shortage of pharmacists, future considerations may include expanding the responsibilities of these staff to support implementation of all health-care programs, especially where ART programs are integrated into existing systems.
To support ART scale-up in settings where pharmacists are in short supply, the national pharmacy department will need to work with ART program managers to decide on the optimal role for each cadre of pharmacy staff and the number of each cadre needed for ART scale-up. Preservice curricula and in-service training materials for pharmacists and other levels of pharmacy staff will also need to be aligned to match competency standards with the recommended scope of practice for each cadre.

SUPPORTING ART INTRODUCTION AND SCALE-UP AT THE FACILITY LEVEL

Involving the pharmacy staff at the facility at early stages of planning and throughout implementation is crucial to a successful start-up and also promotes ownership and sustainability. As countries move to decentralize ART services to the primary health-care level, where pharmacists are scarce, the identification of pharmacists at the provincial or district level who can provide technical oversight and support to pharmacy staff at new ART sites is an important step. For example, in South Africa, almost all provinces have a pharmacist providing oversight of HIV/AIDS pharmaceutical service activities. Furthermore, initiatives to explore ARV dispensing and counseling by pharmacy assistants in primary health-care clinics and identify effective mechanisms for supervision are under way. Approaches to enabling pharmacists to fulfill this new role are discussed later in the chapter. Ideally, the pharmacists should have experience in introducing ART and managing scale-up and be able to anticipate constraints and recommend strategies to address problems that commonly occur.

The primary role of the pharmacists providing technical oversight will be to train and mentor the staff that will be responsible for managing and dispensing ARVs at new sites. In addition, they can assist pharmacy staff and the ART team to do the following:
- Assess the functionality of existing pharmaceutical management systems
- Develop implementation plans that prioritize and address gaps
- Quantify ARV and other supply needs
- Calculate storage needs for ART start-up and expansion
- Adapt and test SOPs, job aids, and recording and reporting forms
- Introduce tools to monitor adherence
- Identify needs for information resources—for example, ART guidelines and drug information for medication counseling
- Implement monitoring and reporting of medication errors, suspected adverse reactions to medicines, and other medication-related events
- Address emerging problems as patient numbers increase

PHARMACY STAFF AS MEMBERS OF THE ART HEALTH-CARE TEAM

Pharmacists and other pharmacy staff are essential members of facility ART committees or multidisciplinary teams and make important contributions to decision making on program management issues and clinical aspects of patient care. In developing countries, the role played by pharmacy staff, and particularly their degree of clinical involvement, varies considerably depending on the cadre of staff that participates and their individual capabilities and motivation. Pharmacists providing technical oversight to sites without pharmacists can mentor and assist the pharmacy staff to contribute more broadly to the ART team.

Experience has shown that including pharmacy staff in the ART team enables them to manage medicines and supplies more efficiently. For example, the team can assist the pharmacy staff
to quantify ARV needs by identifying potential changes in prescribing practice and developing and validating assumptions for expansion. Constraints at the pharmacy that may limit scale-up, such as staff shortages or lack of storage space, can be communicated to the team early on. Furthermore, health provider roles in the ART program—for example, in ART counseling—can be reviewed to identify gaps and eliminate unnecessary duplication to improve efficiency. Other benefits include improving cross-departmental coordination for the program, such as through streamlining the management and follow-up of clients who present for postexposure prophylaxis. As countries work to strengthen pharmacy systems and collect, analyze, and report data, the pharmacy role in providing information to other members of the healthcare team (for example, on ARV consumption or prescribing practices, including characteristics of patients) is increasingly appreciated. One of the key challenges is to present the data in a format that is useful to others without overwhelming the workload of existing staff.

In many resource-limited countries, the clinical role of pharmacists is evolving, allowing them to make important contributions to decision making on treatment and care and case reviews, as well as to provide scientific updates and reviews of rational ARV use, including adherence. However, their level of involvement is generally uneven among facilities. Emerging activities include reviewing the incidence of ART-related adverse events at the facility, coordinating medication event reporting, and contributing to operations research. Pharmacists are very often the link between the ART team and the facility Pharmacy and Therapeutics Committee (PTC) and play an important role in providing information for PTC decision making on facilityformularies and lists.

To be recognized as full members of the healthcare team, pharmacists and other pharmacy staff need to increase their competencies but also adopt new attitudes. These requirements are discussed later in this chapter.

**MANAGING MEDICINES AND SUPPLIES AT ART SITES**

Supply management activities, including procurement and distribution, continue to be important functions for pharmacy staff, and the adequate and continuous availability of quality ARVs is critical to the success of any ART program. In many resource-limited countries, pharmacists still devote much of their time to supply management; however, given the shortage of pharmacists discussed earlier in this chapter, some of these responsibilities are now being delegated to other cadres of pharmacy staff. In countries where responsibilities are being realigned, pharmacists still play a key role in supervising supply management activities, problem solving, assisting in complex tasks such as ARV quantification, and developing new methodologies, tools, and approaches to improve supply management practices.

**THE ROLE OF THE PHARMACY IN SUPPORTING PATIENTS ON ART**

Since the mid-1970s, the focus of pharmacy practice has been shifting from dispensing and inventory management to the provision of services and functions—some traditional and others new—that serve individual patients. In most developed countries and some developing countries, the pharmaceutical profession is working to implement patient-centered services or pharmaceutical care, namely, “the responsible provision of drug therapy for the purpose of achieving definite outcomes that improve or maintain a patient’s quality of life.” Successful medication therapy requires individual therapeutic decisions, reaching agreement with the patient on outcomes and how to achieve them, and patient monitoring. These are all activities...
to which pharmacists increasingly contribute. In resource-limited settings, pharmaceutical care has, until recently, been mainly limited to pharmacists providing clinical pharmacy services in hospitals. However, the introduction of the ART program is increasingly serving as a gateway to strengthening practices and expanding patient care activities at all levels of the health-care system, often to the benefit of other health-care programs. Pharmacists and other pharmacy staff are progressively attaining the training, tools, resources, and supportive supervision needed to empower them to expand their role in ART care.

Key roles of the pharmacy staff include the following:
- Monitoring ART prescriptions for appropriateness and discrepancies
- Dispensing ARVs in appropriate packaging with clear instructions
- Providing medication-related counseling, including reinforcing adherence and advising on potential side effects and drug-drug interactions
- Providing drug information to providers and patients on request

Evolving roles include the following:
- Monitoring adherence to ARVs; working with patients and other providers to address difficulties
- Identifying and following up on patients who do not return for refills of their ARVs
- Working with providers and patients to identify, manage, and report adverse drug reactions and drug interactions
- Active dissemination of drug information to patients and providers
- Contributing to decision making on treatment and care for individual patients

PREPARING PHARMACY STAFF FOR A NEW ROLE

Early experiences in expanding the role of pharmacists in ART at the facility level identified training, adequate staffing levels, and access to up-to-date information as essential requirements for success. As countries move to reorient the role of the pharmacist and other cadres and to standardize and institutionalize these changes, additional policy and human resource issues need to be addressed.

Policies and Legislation

A legislative framework, together with supporting policies and procedures that define the new structure and describe how the reallocation of tasks for pharmacy staff will work, is required to standardize practices and enable each level of the health-care system to implement the changes. Policymakers will need to decide the optimal role for each cadre and the appropriate skills mix needed at each level and develop a structure to provide supportive supervision and technical oversight as staff take on new responsibilities. Legislative changes may need to be made—for example, to enable pharmacy staff other than pharmacists to dispense certain medicines.

Human Resources

Job descriptions need to be updated to reflect new responsibilities and, along with SOPs, are important for effective technical oversight and supportive supervision. Adequate staffing levels are essential to enable staff to take on new roles, such as adherence monitoring or technical oversight at other sites. An important first step in determining staffing levels is to ascertain the ratio of each cadre to the number of tasks to be completed or patients to serve. Eliminating unnecessary tasks and duplication of efforts in order to increase the efficient use of existing staff can also facilitate the reallocation of tasks.
Supporting the Expansion of ART Services in South Africa

In South Africa, the government is working with partners and stakeholders to down refer patients who are stabilized on ART from hospitals to primary health-care (PHC) clinics. In addition to reducing the patient load for the hospital’s pharmaceutical service, this strategy can also reduce transportation costs for patients returning to collect prescription refills. However, the shortage of pharmacists at PHC clinics has led to the increased use of the pharmacy’s assistants and nurses to support the expansion of the ART program and ensure that patients can get their medication. A number of different approaches are being explored.

In one approach, prescriptions are prepared at a nearby hospital and delivered to a PHC clinic closest to the patient’s home or place of work. Prescriptions are packaged with appropriate information by hospital pharmacy staff and delivered to the local clinics. At the clinic, pharmacist’s assistants or nurses dispense the ARVs and review patients’ treatment progress. The PHC clinic returns progress reports and uncollected medication to the hospital.

There is also a movement toward the initiation of ART by nurses at the PHC level. In some PHC clinics, nurses who have dispensing licenses and have been trained on HIV/AIDS dispense ARVs to patients who have been on ART for longer than six months and have been down referred to continue treatment. The nurses reinforce adherence at every visit, monitor patients for adverse events, and refer them for management of adverse events should they occur. Some changes to the applicable legislation and the National Essential Drugs List are needed to support this initiative.

In the Western Cape Province, an initiative is under way to develop a model in which pharmacist’s assistants dispense ARVs in PHC clinics under the indirect supervision of a pharmacist. Additional training is being provided to the assistants, and job descriptions, SOPs, and monitoring tools are being developed to set the standards for pharmacy practice and facilitate effective oversight.

Another model in use in South Africa is one in which a pharmacist visits the PHC clinic once a week to dispense prescriptions for ARVs or to check prescriptions that have been prepared by a pharmacist’s assistant. Prescriptions may be handed to the patient by either the pharmacist or nurses working in the PHC clinic.

Shifting Tasks to Address Severe Shortages of Pharmacists

In 2003, Médicins Sans Frontières and the Nelson Mandela Foundation, in partnership with the Department of Health of the Eastern Cape, initiated a program to provide ART through primary health-care clinics in Lusikisiki, South Africa. Because of a shortage of skilled health-care workers, tasks were shifted to make the best use of available human resources. The traditional functions of the pharmacist in HIV/AIDS care include managing the supply of medicines and overseeing prescriptions, while pharmacy assistants have a limited role and dispense medicines only under the supervision of a pharmacist at a hospital. The Lusikisiki program, however, utilized a hospital pharmacist to provide coaching to pharmacy assistants, whose responsibilities included managing the medicine supply, dispensing prescriptions, and, in some cases, checking adherence.

Capacity Building
Pharmacy staff will require training or retraining to build their skills and knowledge and to adopt essential attitudes to successfully take on new responsibilities and expand their role in ART. Training curricula will need to be aligned with new competency standards and scopes of practice for each cadre of pharmacy staff. Pharmacists will need good leadership, management, budgeting, and communication skills to mentor and assist other cadres to take on new responsibilities for the ART program. For effective medication counseling, staff need good communication and problem-solving skills to assist patients to achieve and maintain high levels of adherence. In addition to preservice and in-service training to capacitate pharmacy staff to take on new roles, they will need a mechanism to stay up-to-date with scientific advancements and changes in recommended practices. Pharmacists will need to be visible, responsible, and committed to maintaining competencies in order to play a larger role in the ART health-care team. Required changes in attitudes for all staff will include a commitment to confidentiality and patient-oriented, rather than task-oriented, practices.

Resources
An essential requirement for providing pharmaceutical care to ART patients is an information system that collects patient-specific data and documents interventions and medicines dispensed at the pharmacy. Pharmacists and other pharmacy staff need access to up-to-date information, SOPs, and job aids (e.g., pediatric ARV dosing tables) to assist them to take on new tasks. Other requirements include a confidential counseling area and validated measurement tools for monitoring adherence in resource-constrained settings.

Summary
Experiences to date have shown that pharmacists and other pharmacy staff have an important role to play in ART care in resource-limited settings by promoting appropriate use and ensuring availability of quality and efficacious medicines. To make the most efficient use of available staff, the roles of
the pharmacist and other pharmacy staff will need to be realigned. However, policymakers may need to be convinced of the value of an expanded role for pharmacy staff and will want to know the cost implications and the feasibility of implementing the necessary changes. Operations research to develop scalable models, answer important questions, and document benefits such as increasing the job satisfaction of pharmacists to slow down migration to the private sector and overseas is urgently needed.

MONITORING, EVALUATION, AND QUALITY OF CARE
The Third One: Monitoring and Evaluation of HIV Programs

John Puvimanasinghe, Wayne Gill, and Eduard Beck

Contributing Authors: Kelvin Sikwibe, Hermann Bussmann, James Guwani, Masauso Nzima, Matthew Warner-Smith, Owen Kaluwa, and Kathi Kotello

Introduction by Deborah Rugg, Chief, Monitoring and Evaluation Division, Joint United Nations Program on HIV/AIDS (UNAIDS), Geneva, Switzerland.

The recent rapid expansion of available resources to fight the global AIDS pandemic has brought with it a commensurate expectation from the global community for greater accountability and more effective and efficient programs. Monitoring and evaluation (M&E) activities play a crucial role in fulfilling those expectations by answering three key questions: “Are we doing the right things?” “Are we doing those things correctly?” and “Are we doing them on a large enough scale to make a difference in controlling this disease?” M&E activities are being implemented at global, national, and subnational levels and have greatly improved our understanding of the HIV epidemic and related responses. In resource-limited settings, where HIV has had the most devastating impact, there has been notable progress in M&E practice following nearly a decade of intensive efforts to strengthen activities. A major breakthrough occurred as a result of the shift from a surveillance-dominated approach to a more comprehensive, system-building approach. The latter approach focuses on the variety of data needed to inform HIV resource allocation and programming to allow for transparency and corrective adjustments in the HIV response. Establishing and maintaining a comprehensive M&E system requires a long-term vision, careful planning, and a phased implementation; in other words, not everything can be done at once. Leadership and M&E advocacy, adequate and skilled staff, as well as sustained funding are all needed to institutionalize M&E and ensure the use of M&E data to improve programs.

This chapter highlights some of the main principles, conceptual frameworks, and M&E methods currently in use. Since much of the HIV M&E efforts to date have focused on monitoring, with insufficient attention paid to evaluation, it includes a discussion of the contributions of monitoring, evaluation, and surveillance linked to a public health questions approach to M&E (i.e., the “M&E staircase” described later in this chapter). While indicators are cited as important measures of progress, they are put in their rightful place within a comprehensive M&E system, which also needs to embrace, for example, qualitative methods and data triangulation. The “Third One” principle (i.e., one national M&E system) emphasizes the need for
a coordinated effort to link and unify the various M&E activities in a country. Only then can a synergistic M&E system be realized that generates the essential information for directing and improving programs and ensuring accountability. This chapter discusses essential elements in developing the Third One at the national level.

**EVOLUTION OF MONITORING, EVALUATION AND SURVEILLANCE METHODOLOGIES FOR HIV/AIDS PROGRAMS**

One of the greatest challenges in HIV prevention, care and treatment, and mitigation is determining what impact efforts have had on the epidemic. In the late 1980s and early 1990s, it was assumed that biologic indicators could be used to evaluate prevention programs. Toward that end, many evaluation plans called for collecting data on the incidence and prevalence of HIV and other sexually transmitted infections both pre- and post-intervention. Information on self-reported behavior was collected as well. However, most M&E was conducted in a piecemeal fashion.

In the early 1990s, the World Health Organization / Global Program on AIDS (WHO/GPA) collaboratively developed a set of biological and behavioral prevention indicators for national AIDS control programs as well as standardized protocols to facilitate cross-country comparisons. However, it became increasingly evident that lack of M&E resources and experience was resulting in an inconsistent and incomplete understanding of the impact of prevention efforts. To help address those shortcomings, Family Health International pioneered the behavior surveillance survey. This method involved a series of repeated behavioral surveys in key target groups. Behavior surveillance surveys enabled national programs to track trends in HIV risk behaviors and assess the combined impact of various HIV interventions in a country. These second-generation surveillance systems monitor risk behaviors, using them to warn of or explain changes in the levels of infection. Second-generation surveillance uses data from behavioral surveillance to interpret data gathered from sero-surveillance efforts. In addition, the key indicators survey was developed by the United States Agency for International Development (USAID)–funded MEASURE (Monitoring and Evaluation to Assess and Use Results) program to help monitor and evaluate population and health programs. In addition to these useful tools, a limited number of timely qualitative studies were undertaken, which provided a much-needed look into the complexities of sexual and related behaviors to help explain HIV trends in their respective settings. In other cases, secondary follow-up analyses were conducted using data sets from previous studies or programs.

In the early-to-mid-1990s, it was becoming increasingly clear that the world was facing a complex, multifaceted HIV pandemic. Variations in infection patterns by region and often within smaller boundaries of a country were not uncommon. To enhance the sophistication of surveillance in order to match the complexities of the epidemic, processes were developed and refined for cross-referencing and understanding the epidemic from various angles. There was also a recognized need to complement the quantitative and behavioral data with qualitative information from in-depth interviews, focus group discussions, and rapid ethnographic studies. To address that need, an approach, commonly known as data triangulation, was developed that entails the “nesting” of qualitative data within a quantitative data collection plan, thereby allowing for a more well-balanced interpretation of HIV data.

As our understanding of the epidemic evolves, there is recognition that a comprehensive approach to monitoring and evaluation requires
multiple techniques and data sources so that the relationship between biomedical, behavioral, and socio-demographic data can be better examined and understood. Yet the absence of a common operational M&E framework in most countries has hampered efforts toward such a comprehensive approach. According to the Three Ones, the landmark agreement made in 2004 between donors, developing countries, and UN agencies promoting universal coordination in the fight against HIV, the Third One is the existence of an agreed-upon M&E system for overall national monitoring and evaluation.²

**PRINCIPLES OF MONITORING AND EVALUATION**

**Introduction to Planning, Monitoring, Evaluation, and Surveillance**

Monitoring and evaluation is a natural step in the program planning and implementation process. When M&E is incorporated into a program design, this helps to ensure that the project is clearly defined and articulated, is well researched, and can be objectively measured and verified with sound data collection methods. In this way, M&E provides an objective basis for describing the project and its accomplishments to others. Planning an intervention and designing an evaluation strategy are inseparable activities.

*Monitoring* can be defined as the routine tracking of information about a program/project and its intended effects. It measures the progress made toward achieving the objectives of the program/project. *Evaluation* is the periodic, in-depth, and systematic collection and assessment of information related to program activities, characteristics, and outcomes in order to make judgments about the program, improve program effectiveness, and inform decisions about future programming. This information helps to enhance understanding of a particular program or project in terms of its formulation, its characteristics, and its worth or merit. In this way, monitoring systems are a basis for determining the factors responsible for optimal or suboptimal program performance.³

The usefulness of M&E is diminished if it is performed solely to meet donor needs. The results, conclusions, and lessons learned derived from M&E are invaluable to program managers, target populations, and other stakeholders. M&E should be seen as an essential function of program management as it provides insight into what is and is not “working,” and may help identify ways to refocus strategies. M&E is *not* about assigning a grade at the end of a project but, rather, should be seen as a valuable tool for improving the effectiveness of the program, as well as one that helps to develop the capacity of individuals, organizations, and communities. M&E is, simply put, a process to determine the impact and effectiveness of a project in order to apply the lessons learned.

The following is an outline of the basic steps involved in program planning along with references as to how each element links to M&E.

**Step 1: Define the context of the problem.** Collecting information related to reducing the impact of HIV in the local context helps to identify problem areas and prioritize solutions—or potential interventions—that might address the problem. This is sometimes called a *situation analysis* or *assessment.* Whatever information gaps exist at this stage will have to be resolved early in project implementation through *formative research.* This research may form part of the *baseline assessment* against which progress can be determined.

**Step 2: Assess organizational and institutional capacity.** The success of a project depends not only on sound project design but on the strengths of the implementing organizational and the institutional environment in the country or region. An
It is in this step that decisions are made regarding which qualitative and/or quantitative methods will be used to collect data. The OVs and the MoVs constitute the monitoring and evaluation plan.

The M&E planning process should set out to answer the following questions:

- What development objective (i.e., goal or overall objective) do we want to achieve in the long run?
- What benefit (i.e., project purpose) at the level of the key stakeholders do we want to achieve upon completion of the project cycle?
- What services (i.e., outputs) do we need to provide for this benefit?
Figure 1 depicts the links that must be formed between planning and M&E if a program strategy is to be successfully implemented. This model assumes that all required resources are strategically placed to perform the requisite functions at all levels of project/program implementation.

Despite prescribed designs for linking activities, few countries have successfully built fully functional M&E systems. In the east and southern Africa region, Botswana, Malawi, Rwanda, Swaziland, Tanzania, Zambia, and Zimbabwe have all developed functional M&E systems—albeit with varied degrees of advancement—which also incorporate an aspect of planning.

Surveillance (i.e., impact monitoring) is the continuous monitoring of the occurrence and distribution of diseases and other conditions of ill health and their determinants for effective disease control and prevention. Surveillance systems in most of the countries in the east and southern Africa region are well developed and are used to generate reasonably good quality information on the HIV epidemic. HIV surveillance has been in operation in these countries since the 1990s. However, only a few countries in the region, including Botswana, Malawi, and Mozambique, have undertaken or are in the process of instituting second-generation surveillance activities to better understand their epidemics. Second-generation surveillance consists of collecting and comparing both biological and behavioral data, which enables a better understanding of the epidemic. So far, these findings have been an important planning tool for program managers and policymakers in their respective countries.

Components of HIV Programs in the Context of M&E

A program can be considered as a set of processes for transforming resources into results. In M&E terminology, program resources are referred to as inputs; program activities or operations as processes (i.e., activities); and results as outputs (i.e.,
Outputs are the immediate results obtained by the program through the execution of activities (e.g., number of commodities distributed, number of staff trained, number of people treated).

Outcomes are the short-term or intermediate results obtained by the program through the execution of activities (e.g., number of staff implementing new guidelines, frequency of stock-outs).

Impact is the long-term effect, such as changes in health status.

Any or all of these resources may be a priority for a given program, and they are defined as follows:

- **Inputs** are the resources going into conducting and carrying out the project or program. They could include staff, finance, materials, and time.
- **Processes** are the set of activities in which program resources (human and financial) are used to achieve the results expected from the program (e.g., number of workshops held).
- **Outputs** are the immediate results obtained by the program through the execution of activities (e.g., number of commodities distributed, number of staff trained, number of people treated).

In general, inputs, processes, and outputs are the three domains of information required in a monitoring system. Outcomes and impact are the domains of information required in an evaluation.

A useful starting point for M&E activities is the use of the M&E “staircase” framework as the basis for articulating the questions that need to be asked at each step of the M&E process. As depicted in Figure 2, the staircase framework is made up of eight steps: (1) problem identification; (2) determination of risk factors; (3) research on what interventions work (i.e., efficacy and effectiveness); (4) definition of specific interventions and resource needs; (5) assessment of quality of program implementation; (6) monitoring the extent of program outputs; (7) examination of program outcomes and program effectiveness; and (8) determination of overall program effects and collective effectiveness.1
Although few if any African countries are adequately covering the steps as depicted in Figure 2 and/or achieving significant success in the application of a formal M&E framework, some countries have successfully established mechanisms that generate useful data for improving program activities. In Botswana, for example, a multisectoral technical working group makes decisions about harmonization of indicators for the national HIV response, while at the same time churning out information products for policymakers. In so doing, M&E has become more accessible to government officials, thus generating a greater demand for information (see the chapter titled “The Third One in Practice: Monitoring and Evaluation of the Botswana National HIV Response”). Ethiopia has produced an information product (a succinct and user-friendly annual M&E report) from its national M&E system, albeit with a health bias.” In Zambia, Malawi, Ethiopia, Rwanda, and Botswana, the sub-national levels (provinces and districts) have started using M&E information to develop plans for HIV responses at these levels. In Botswana and Zambia, the local government uses systems that generate relevant data for development planning and budgeting.

Yet most efforts, regardless of the level at which they occur, are focused on monitoring rather than evaluation. To correct this imbalance, a deliberate shift in the direction of evaluation is needed. That will lead to a better understanding of the trends of the epidemic and the factors responsible for what is being observed. For example, it is imperative that countries are up to date on emerging issues, such as the impact of male circumcision on HIV infection and routes and modes of HIV transmission. At another level, a radical redesign of response strategies is needed, with a particular focus on prevention. The current work in Botswana to develop a national evaluation agenda represents a move in that direction.

**The Logical Framework Approach**

As mentioned earlier, the LFA is a common conceptual framework used by many donors and programs. The LFA is useful in generating clearly identified objectives and organizing them in a hierarchical framework that moves from the general (longer-term) to the specific (shorter-term). The LFA is a tool for analysis, presentation, and management of activities that can help planners and managers to

- analyze the existing situation during activity preparation;
- establish a logical hierarchy of means by which objectives will be reached;
- identify the potential risks to achieving stated objectives, including sustainable outcomes;
- establish how outputs and outcomes might best be monitored and evaluated;
- present a summary of activities in a standard format (if desired); and
- monitor and review activities during implementation.

Developers of the LFA intended it to be used as a tool for strengthening project design, implementation, and evaluation. The LFA may be used to involve primary stakeholders in a participatory planning process or to summarize the key features of a project design; it can also be used as a monitoring and evaluation tool. The goal of evaluation specialists in the LFA process is not to define the proposed objectives at each level of activities, but rather to facilitate the process by which program managers and stakeholders themselves collaboratively define the objectives. If the objectives are felt to be arbitrary or chosen by others, there will be no ownership and those involved will be less motivated to achieve the objectives and to buy into the process of measuring progress.

The LFA enhances planning, analysis, and communication by (1) clarifying the purpose of the project, (2) identifying information requirements,

(3) clarifying the definition of the project, (4) analyzing the project setting at an early stage, (5) facilitating communication between all parties, and (6) identifying ways that the failure or success of the project can be measured.5

The LFA would be incomplete without the use of a practical organizing frame or matrix. This frame is known as the logframe matrix, or simply, logframe. The logframe is designed as a four-by-four matrix. Along the horizontal axis are objectives, indicators, means of verification, and assumptions; along the vertical axis are four hierarchical levels of objectives. Table 2 provides an illustration of the logframe together with accompanying steps for constructing the matrix at the program design stage.

It is worth noting that the process of developing the logframe matrix is even more valuable than its use during implementation. The following are a few useful points to keep in mind during the development of the matrix6:

---

Source: Adapted from Van Leeuwen.6
Define the key assumptions at each level (working upward).

Check that the vertical logic still holds given those assumptions. Begin at the lowest level of objectives and consider potential constraints and name them. A useful methodology to determine “assumptions” is the following: if A (activity) takes place and B (assumption) is in place, then we can accomplish our higher-level objective C (output).

First define indicators for the objectives, then for the outputs (or check that these are specified with targets), then for the goal.

Define the means of assessment at goal, objective, and output levels.

Check the “horizontal logic” across each row.

Put inputs and costs for the activities in the bottom row (i.e., the budget summary).

Review the logframe design in light of past experiences with similar efforts.

Defining Goals and SMART Objectives

The goals and objectives of a program are a good starting point for setting up an M&E system. Goals and objectives, particularly in the context of the logframe, establish a foundation of what is measurable from the standpoint of M&E. The goal is the higher-level objective, stated generally, that describes the intended result of a program. Goals are achieved over the long term (5 to 10 years) and through multiple programs. The objective is a specific, operationalized statement detailing the desired accomplishment of the program. A good question to ask when defining objectives is “What changes will occur because of our activities?” A properly stated objective is action oriented, starts with the word “to,” and is followed by an action verb. Objectives address questions of “what” and “when,” but not “why” or “how.” Objectives are stated in terms of results to be achieved, not processes or activities to be performed. Without clearly defined objectives, it is virtually impossible to conduct effective M&E activities. When objectives are not clearly defined, the indicators that follow (even if well crafted) will be meaningless and thus produce little if any valuable information. To facilitate the process of clearly defining objectives, the SMART principles are used:

- **S** specificity: Is it specific? Does it cover only one rather than multiple activities?
- **M** measurability: Can it be measured or counted in some way?
- **A** attainability: Is the objective actually doable? Can we achieve this goal?
- **R** relevance: How important is this objective to the work that we are doing? How relevant is it to achieving our goal?
- **T** time: Does the objective include a time frame for when the objective will be achieved or for when the activity will occur?

The effectiveness of M&E will be greatly enhanced by good project design utilizing SMART goals and objectives. Conversely, a good M&E system will bring focus and clarity to goals and objectives, helping the project to get back on track.

Defining Indicators

Once the SMART objectives have been identified, the indicators for the program can be defined. An indicator is a unit of information that facilitates measurement over time, enabling the M&E system to document change. As such, indicators provide evidence of how much has or has not been achieved. Such measures are usually quantitative (numerical) but may also be qualitative (narrative) observations. Indicators enable a large amount of data to be reduced down to its simplest form.

It is important to reiterate that without clearly defined objectives, SMART objectives, the resultant indicators, although they may be well crafted, will yield meaningless information. This highlights the
importance of integrating M&E considerations into project design. Indicators provide a simple and reliable means to measure achievement, reflect the changes connected to an intervention, or help assess the performance of a development actor. Indicators also enable managers to track progress, demonstrate results, and take corrective action to improve service delivery.

Once indicators have been formulated, they are used as a basis for setting performance targets and assessing progress toward achieving those targets. In this way, indicators provide an “early warning system” that allows program managers to identify problems and take corrective action when performance targets are not met. Indicators also facilitate benchmark comparisons between different organizational units and districts over time. Yet in most cases, indicator data are of limited value in identifying why changes occur. At best, indicator data can suggest whether or not an in-depth evaluation or review is needed.9

Ideally, indicators should highlight key elements of change that can be attributed to program activities. Indicators should be readily available from existing data sources or should be possible to obtain on a regular basis at low cost. Efforts should be made to ensure that the indicator is well defined, easy to collect, easy to interpret, and capable of demonstrating changes over time.

Indicators should be:
- **Valid**—measure the condition or event they are intended to measure;
- **Reliable**—produce the same results when used more than once to measure the same condition or event, all things being equal (e.g., using the same methods, tools, or instruments);
- **Specific**—measure only the condition or event they are intended to measure;
- **Sensitive**—reflect changes in the state of the condition or event under observation;
- **Operational**—can be measured or quantified with developed and tested definitions and reference standards;
- **Affordable**—can be measured at a reasonable cost; and
- **Feasible**—data collection can be easily carried out.

Indicators should not be:
- used to define or conceptualize a project;
- overly complicated—key stakeholders should be able to understand them;
- developed from scratch, with much effort;
- derived for their own sake (e.g., are included in a proposal but never used by program managers); and/or
- so numerous that they are overwhelming for program managers to utilize.

Characteristics of strong indicators include:
- able to provide an at-a-glance indication of a program’s status;
- comparable across time;
- an effective means to measure progress toward objectives;
- comparable between locations (e.g., between districts or countries);
- easily understood by decision makers;
- easily communicated;
- inexpensive to collect.

Characteristics of weak indicators include:
- superficial measures of performance;
- lacking explanatory power (i.e., further investigation required to identify the causes of change in indicator value);
- open to misinterpretation.

Accurately and regularly measuring just a few indicators will be more helpful to a program than generating an extensive list of indicators that are
never used. **Selection of indicators is a critical step in the program planning and M&E design process.** It is advisable that the selection of indicators be done in a participatory way with the involvement of key program stakeholders.

**Appropriate Use of Indicator Data**

Indicator data are used as a management tool at a variety of levels within a given program, from the point of service delivery up to the subnational or collaborating partner, national management, and international donors. At the point of service delivery, organizations or implementing agencies may be responsible for conducting a formative needs assessment; monitoring of inputs, process, and outputs; collecting and aggregating data from frontline project personnel; reporting to sponsors and partners; and using results for ongoing program implementation. At the collaborating partner level, country offices may be responsible for aggregating and synthesizing results, coordinating M&E activities across projects, reporting to donors, and/or disseminating and using program results. At the national level, the national coordinating body may be responsible for the national formative needs assessment; aggregating results from collaborating partners; providing feedback of results from government-sponsored M&E activities to collaborating partners; maintaining biologic and behavioral surveillance systems; and using M&E results to advocate for policy formulation and changes. This section focuses on the use of indicators at the national, multisectoral level, for use by national coordinating bodies in shaping and guiding national responses.

As illustrated by the M&E pipeline (Figure 3), the number of indicators for which data are collected should be related to the level of effort required to collect the needed information. At the service delivery point, relatively little effort is required to collect data related to program inputs and outputs. However, such data are related specifically to the implementation of particular services and are often unique to that service. As such, program-specific indicators may have limited utility at the national level.

When selecting indicators for the monitoring of the national response, a focus on outcome indicators is appropriate. Although this does not preclude output measures at the national level, only a small number of output indicators that are common across a range of service providers are likely to be of use for guiding the national response. Counts of the numbers of condoms distributed may be an example of such an indicator. More commonly,
outcome measures, rather than output measures, are of more value at the national level. Outcome and impact indicators are difficult to attribute to specific programs and are not necessarily suited to monitoring at the program level. These should be included in the national indicator set and attributed to the response as a whole, and not to specific programs.

Although outcome measures require more effort for data collection and are more difficult to attribute to a particular program, they are more useful than output measures for determining whether the national response to HIV is achieving its desired objectives. Continuing from the previous example, condom use rates are of more value to national coordinating bodies than the numbers of condoms distributed, as they provide a more direct measure of the likelihood of infections being averted. The fact that condom use rates are a function of many factors, including both programmatic (e.g., prevention messages, condom social marketing) and social factors (e.g., female empowerment), is of secondary consequence. From the perspective of a national AIDS coordinating body, it is more valuable to know whether the national response as a whole is achieving its objectives than to know whether a particular program is achieving its particular service delivery targets.

Impact measures, such as incidence, prevalence, and mortality, require the greatest level of effort for data collection and are the most difficult to interpret. As such, they should be collected relatively infrequently and used in conjunction with outcome and process measures.

Minimum Indicator List
Historically there has been a tendency to include too many indicators in the national set. This may be partially explained by the notion that “what gets measured gets done.” Certain indicators can be used to push for different interventions and issues, and as a result, some may advocate for unnecessarily large numbers of indicators to be included in the national set on the assumption that this will drive programming in a given area. However, this trend has hampered the development of national systems, as the collection, interpretation, and reporting of large numbers of indicators is costly and impractical. Although recognizing and responding to the concerns of lobbyists is important, of even greater importance is limiting the number of indicators in the national set so that data collection, interpretation, and reporting is feasible and efficient.

The proliferation of indicators included in national sets or defined by international agencies over the previous two decades of the HIV epidemic undermine one of the main strengths of indicator data, namely, the ability to compare data between programs and across time. In response to this proliferation, a global process to review indicators for monitoring HIV programs was recently undertaken by the Joint United Nations Program on HIV/AIDS (UNAIDS) Monitoring and Evaluation Reference Group. The objective of this process was to consolidate the large number of indicators into a shortlist of those proven to be valid, reliable, and feasible to collect. Indicators from the shortlist were then selected for international reporting and recommendations made for indicator selection for national programs.

The national and international agencies represented on the UNAIDS M&E Reference Group reviewed more than 400 indicators and selected a set of 45 deemed most appropriate for monitoring the response at the national level. The recommended set includes the 25 United Nations General Assembly Special Session (UNGASS) core indicators, plus an additional 20 program indicators.

A further impediment to the operationalization of national monitoring systems has been that indicators are often defined without consideration for the feasibility or practicality of data collection.
Many indicators that do not have accessible data sources have been included in national indicator sets and are subsequently never reported. At the national level, indicators should be selected from the existing monitoring systems of national programs or from regularly planned surveys, such as bio-behavioral (second-generation sentinel) surveys used in the national surveillance system or national censuses.

As previously mentioned, not all indicators needed for effective program management should be reported to the national level. A classic example of this is the cascade of indicators used for monitoring prevention of mother-to-child transmission (PMTCT) programs. From a management perspective, it is important to monitor each step of the cascade. At the national level, where PMTCT is one of a number of strategies in the national response, it is unfeasible, impractical, and unconstructive to try to consider each of these steps. Since the main concern of the national coordinating body is the effectiveness of the national response, including a single indicator for PMTCT coverage and impact is sufficient. If the value for that indicator is low, further investigation of the cascade of indicators and additional evaluations may be appropriate. Figure 4 shows a sample PMTCT indicator cascade.

As countries scale up their national HIV response toward the goal of universal access, monitoring of the epidemic and the response is of paramount importance. Such efforts will enhance the effectiveness of interventions, inform policies and programs, and promote accountability. Building upon related international efforts, such as UNGASS, the WHO has developed a framework designed to facilitate the generation of standard information that would monitor the health sector’s progress toward universal access. The framework proposes a core set of indicators to monitor scale-up and includes 11 UNGASS indicators and seven others collected by the WHO/UNICEF Inter-Agency Task Team.\textsuperscript{10,11}

- Percentage of pregnant women who receive antenatal care (ANC) services
- Percentage of pregnant women receiving ANC services who are offered an HIV test
- Percentage of pregnant women receiving ANC services who undertake an HIV test
- Percentage of pregnant women receiving ANC services who test positive for HIV
- Percentage of HIV-positive pregnant women receiving ANC services who are offered HIV prophylaxis
- Percentage of HIV-positive pregnant women receiving ANC services who complete a full course of HIV prophylaxis
- Percentage of infants born to HIV-positive pregnant women receiving ANC services who are given HIV prophylaxis
- Percentage of infants born to HIV-positive pregnant women who are HIV-infected
Selection and Construction of New Indicators
The selection of new indicators should be done only when there are no suitable indicators currently in use within program-monitoring systems or being provided by regular national surveys. This may occur, for example, when a number of programs contribute to a desired outcome but none specifically measure that outcome. An example may be community programs providing care for orphans and vulnerable children. Among the objectives of such programs might be a reduction in the disparity of school attendance of orphans compared with non-orphans. The ability to measure orphans’ and non-orphans’ school attendance is well beyond the capacity of community programs. It might therefore be appropriate in this instance to define an outcome measure and advocate for its collection by national authorities.

Participation of key stakeholders in constructing and defining indicators is important, since they are then more likely to understand and use the indicator for management decision making. Often it is necessary to make a trade-off between picking the optimal or desired indicators and having to accept the indicators that can be measured using existing data. After more than 20 years of the HIV pandemic, more than 400 monitoring indicators have been developed and are used by international agencies or recommended in indicator manuals. It is therefore unlikely that it would be necessary to reconstruct an indicator for use for national-level monitoring. However, if all stakeholders agree that, after reviewing the indicators currently in use or previously defined, a new indicator should be constructed, the SMART principle should be followed.

Selection of Data Collection Methods
Choosing the appropriate method of data collection for indicators is as critical as choosing the indicators themselves. The perfect indicator is useless if the information cannot be obtained with the time and resources available to the project. The indicators chosen for measuring program achievements should dictate which methods are used to gather the relevant data. There are two methods, or approaches, for collecting data—quantitative and qualitative:

1. **Quantitative methods** are those that rely on structured or standardized approaches for the collection of data that are often analyzed numerically. Some common quantitative methods include censuses, population-based surveys, and facility inventories. Quantitative data are most useful for providing precise and broad data about a whole population, objective measurements, quantities, and what has happened.

2. **Qualitative methods** gather in-depth, descriptive information about how people function and how different aspects of their lives and relationships are linked together. Some common qualitative methods include participatory learning and action (PLA) and participatory rural appraisal (PRA) activities, focus group discussions, and semistructured interviews. Qualitative data are most useful in determining why things have happened and understanding the underlying dynamics of a situation. Qualitative methods help to contextualize the data derived from quantitative methods. This means that they help to understand and explain the phenomena better.

Quantitative and qualitative methods can and should be used in a complementary fashion to investigate the same phenomenon. For example, one might use open-ended, exploratory (qualitative) methods to investigate what issues are most important and the language to use in designing instruments for process evaluation. Alternatively, one might find surprising results in a survey that cannot be explained by the survey data, but might be better explained through open-ended focus group discussions.

Table 3 lists some primary sources of data for measuring indicators.
A written monitoring and evaluation plan describes all of the M&E activities to be undertaken and how they will be carried out. The goals and objectives of the program or project will provide the basis for this plan.

The M&E plan should include the following components:

- A clear description of the purpose for the M&E plan. The purpose statement helps to explain how the development of the M&E plan meets management requirements (the need for strategic information in decision making, evidence-based planning and analysis, donor reporting requirements, program steering).

- Definition of the scope of M&E to be undertaken. This will include considerations for program goals and objectives, primary questions

In addition to those listed in Table 3, other data sources include the following:

- Program data—counts of individuals served or services provided
- Survey data—percentage of the population practicing a behavior or accessing a service
- Estimates—epidemiological models of the size of populations (e.g., the number of people living with HIV, the number of people with advanced HIV infection in need of treatment, the number of HIV-positive pregnant women). The Estimation and Prevention Package for SPECTRUM software developed by WHO/UNAIDS is one tool that can be used to estimate and project adult HIV prevalence from surveillance data.\(^a\)

MONITORING HIV DRUG RESISTANCE

HIV DRUG RESISTANCE IS THE inevitable consequence of the high mutation and replication rate of the HIV virus. In most cases, emergence of drug-resistant mutations occurs during antiretroviral therapy (ART) when the replicating virus is exposed to the pressure of antiretroviral drugs (ARVs) and selects for resistance mutations. While this acquired (secondary) drug resistance is the largest obstacle to the success of ART, the advent of convenient and highly potent ARV drug combinations has greatly reduced the rate of acquired drug resistance.\textsuperscript{12}

Transmitted (primary) drug resistance refers to the presence of drug resistance in HIV-infected individuals who have never been treated with ARVs. The majority of data concerning the magnitude of transmitted HIV drug resistance has to date been obtained in developed countries, where ARV drugs have been widely available for many years.\textsuperscript{13} However, the monitoring of transmitted drug resistance is of paramount importance for developing countries, where population-based approaches to the provision of ART have been more recently adopted.

The brief overview that follows focuses on the monitoring of primary and secondary drug resistance in resource-limited settings where large public ART programs have recently been initiated. Typically, national programs of this type offer standardized, potent first-line combination ART regimens and at least one standardized second-line (protease inhibitor-based) regimen for cases of treatment failure.

Monitoring of Acquired (Secondary) Drug Resistance

Monitoring the emergence of drug resistance among individuals receiving ART is a major challenge for most resource-limited settings. In such settings, which often lack viral load and/or genotypic resistance testing, national ARV treatment guidelines typically guide the management of treatment failure. Since standardized, potent regimens are being used in largely treatment-naïve populations in these settings, it is assumed that treatment failure due to drug resistance can be successfully managed by offering all patients that fail their first-line regimen an alternative, new regimen without the need to perform genotype resistance testing. In 2001, data obtained as part of the Botswana national sentinel surveillance showed virtually no major drug resistance in the population prior to initiating its public ARV treatment program, known as MASA. Longitudinal resistance monitoring data will soon be available from Botswana, and as larger programs in the region initiate ever-increasing numbers of qualifying persons on ART, routine longitudinal tracking of drug resistance will be critical to long-term program success.

While comprehensive documentation and evaluation of treatment failure cases is an essential activity in all ART programs, WHO and U.S. Centers for Disease Control and Prevention (CDC) have developed a standardized, minimum-resource method for sentinel monitoring of HIV drug resistance to be used in selected sites in countries where decisions on
ART regimens are made on a population basis rather than at the level of individual patients. WHO recommends that this population-based resistance monitoring method be performed annually at representative sites within a country to provide important information on the emergence of drug resistance. In accordance with the existing WHO/CDC protocol, a cohort of 100 consecutively selected patients initiating ART in a specific (sentinel) survey site will be followed over 12 months. In addition to routinely collected data, each consenting patient will also have a genotype and viral load performed at baseline and at 12 months.

Drug resistance is integrally linked with ARV medication adherence rates and drug availability. WHO has recommended that all ART sites develop and monitor specific early warning indicators (EWIs) that will assist in assessing whether or not HIV drug resistance is becoming a problem in a particular country. The specific proposed EWIs include the following:

- percentage of people initiated on first- and second-line ART regimens
- percentage of people lost to follow-up
- percentage of people who started first-line drugs and are still on first-line drugs after 12 months
- percentage of people who pick up all prescribed medications on time and who attend all scheduled appointments during a year
- percentage of people who demonstrate optimal adherence (as determined by pill counts)
- drug supply continuity
- proportion of patients who have suppressed plasma viral load 12 months following ART initiation

**Monitoring of Transmitted (Primary) Drug Resistance**

The most accurate method for detecting primary drug resistance involves performing genotypic resistance testing among those identified as being “recently” or “acutely” infected using newer detuned ELISA methodologies. Transmitted resistant virus is very often outgrown by wild-type virus within weeks or months and is not routinely detected using conventional genotypic resistance assays at the time of ART initiation. Two alternative approaches may be used to estimate the proportion of primary drug resistance, one based on identifying and genotyping persons with recent HIV infection in the community and the other based on monitoring the treatment response in patients initiated on ART.

The HIV drug resistance (HIVDR) threshold survey approach recommends monitoring high-risk individuals by socio-demographic criteria in communities with existing high (greater than 50%) ART coverage rates. WHO recommends targeting young women under 25 years presenting for their first pregnancy in settings with high ART coverage rates. While other sentinel groups could certainly be evaluated, the HIVDR survey approach can be easily added to existing annual national sentinel surveillance activities, which many developing countries participate in as recommended by UNAIDS. Specific test algorithms allow for the prediction of population HIVDR by evaluating small total numbers of genotypes (maximum 60). In the future, identification of recent HIV infection utilizing laboratory-based incidence testing will increase the accuracy and convenience of such surveys.
that M&E activities should answer, information needs of various players and stakeholders, and technical capacity for conducting M&E.

- **Selection of indicators and development of indicator protocols.** Indicator protocols would include specification and definition of indicators for each program objective and activity to be monitored or evaluated, identification of one or more data sources for each indicator, identification of the persons or groups responsible for each activity, and timeline of when information on that particular indicator will be collected.
- **Guidelines and procedures for analyzing and disseminating M&E data**
- **Required budget**

Indicator protocols are widely available and accessible on the Internet. For example, the U.S. President’s Emergency Plan for AIDS Relief (PEPFAR) has a set of indicator protocols that are updated annually. Other development partners, such as the World Bank, UNAIDS, The Global Fund, WHO and other UN organizations, have invested time and efforts in developing similar indicator protocols that can be easily replicated or adapted to meet specific M&E needs.

**Program Evaluation**

Program evaluation helps us to understand the broader effects of planned, ongoing, or completed program interventions. While it is generally accepted that a program of any scope can be evaluated, it is important to make certain distinctions from the outset. For an assessment to be considered an evaluation, it must conform to certain quality standards that guide the process and ensure that the information generated is technically sound, given the features that determine the worth or merit of the program.

**Program Evaluation Standards**

Evaluation standards help ensure that program evaluations are properly conducted. The jointly developed U.S. Program Evaluation Standards (US

---

**Specimen Types for HIV Drug Resistance Testing**

Blood specimens used for resistance testing are routinely obtained in collection tubes and processed as plasma aliquots. Epidemiological studies have long relied on the dried blood spot (DBS) approach, which is simple and only requires a few drops of blood to be collected on filter paper. Dried blood spots have the advantage of being affordable, easily obtained (with minimal patient discomfort), and easily stored and shipped for analysis to a designated, qualified laboratory. DBS samples have been evaluated for HIV testing, viral load measurement, and genotypic resistance testing. One potential drawback of DBS is the smaller blood volume available for analysis, especially in ARV-treated patients with a low viral load.

In summary, monitoring of transmitted and acquired drug resistance is of high importance in resource-limited settings. Currently affordable methodologies for HIV drug resistance monitoring are being validated and should become an integral part of HIV surveillance programs.

**Program Evaluation**

Program evaluation helps us to understand the broader effects of planned, ongoing, or completed program interventions. While it is generally accepted that a program of any scope can be evaluated, it is important to make certain distinctions from the outset. For an assessment to be considered an evaluation, it must conform to certain quality standards that guide the process and ensure that the information generated is technically sound, given the features that determine the worth or merit of the program.

**Program Evaluation Standards**

Evaluation standards help ensure that program evaluations are properly conducted. The jointly developed U.S. Program Evaluation Standards (US
formative evaluations provide information for developing or forming a new program or to provide information to assist in revising or modifying an existing program. They are thus conducted during the planning or replanning phase of a program. Examples of strategies used for formative evaluations of HIV programs include needs assessments, situation/response analyses conducted prior to programming, and the midterm reviews of HIV projects or national programs (see Zambian Joint Annual Review sidebar).
THE ZAMBIAN JOINT ANNUAL PROGRAM REVIEW

Program reviews are conducted to obtain an assessment of what is happening on the ground in the multisectoral response to HIV. This is necessary to measure progress on the implementation of strategies at the national, provincial, district, and community levels. The review process itself is also helpful for overcoming delivery bottlenecks by ensuring that corrective action is undertaken in a timely manner. A program review also provides organizations/program managers with the opportunity to review the continuing relevance of programs; interim results with regard to performance indicators; the effectiveness of the approach being used to produce the results; the efficiency of program management, including the delivery of inputs and activities in terms of quality, quantity, and timeliness; and the need for corrective actions where necessary.

Over the past few years, Zambia has conducted a joint annual program review (JAPR) to review progress and agree on priorities for the national response to HIV. The JAPR is a process that brings the government of the Republic of Zambia, the National HIV/STI/ TB Council and partners together to review progress toward targets and objectives laid out in the Zambian National HIV/AIDS Strategic Framework. Following the success of the JAPRs in 2004, 2005, and 2006, the JAPR process has now become increasingly recognized, and used, to bring together cooperating partners and key stakeholders involved in supporting the national responses to HIV.

The JAPR draws almost entirely on existing documentation and ensures that the analysis and conclusions are linked to relevant government processes. A coordination team guides and supports the process and ensures that key documents and summary reports are produced in time for the main JAPR meeting. Data for the JAPR are gathered through a mix of quantitative and qualitative approaches, including literature reviews, primary and secondary data reviews, questionnaires, interviews and focus group discussions with key informants, and selected site visits to collect supplementary data, if necessary, to address specific gaps or questions that arose during the review process.

The following are some of the uses of formative evaluations:

- Assessing the need for an intervention
- Assessing acceptability of an intervention in a particular community
- Determining how best to implement an intervention or project in order to attain the intended objectives

The methods used for formative evaluations include reviews of existing information, focus group discussions, in-depth interviews with key informants, participant observation and short quantitative surveys with structured questionnaires.

On the other hand, summative evaluations aim to examine the effectiveness and/or efficiency in achieving the objectives of a program. They examine the outcome and impact of a project or program and also estimate the relative associated costs. They are normally conducted at the end of an intervention, project, or program. Here are some examples of summative evaluations:
At the planning stage, consideration should be given to the purpose of the evaluation. The purpose of an evaluation should not be limited to criteria, such as “to establish the effectiveness of the nurse-technician ARV dispensing model” or “to establish the impact of integrating TB testing in posttest services for HIV positive individuals.” While criteria are the means by which an evaluation purpose will be achieved, the purpose is an action that is made possible by the evaluation, such as facilitating decision making and learning. Thus the purpose of an evaluation could be, for example, “to help the National AIDS Coordinating Agency formulate a strategic framework for a TB/AIDS referral system” or “to provide a basis for scaling up a community-based HIV testing strategy.”

An important consideration when planning for an evaluation is having a clear understanding of the criteria for the evaluation. There are basically five agreed-upon criteria for any evaluation: effectiveness, efficiency, relevance, impact, and sustainability (see sidebar on Evaluation Criteria). There are, however, other criteria that can be developed beyond these five. For instance, additional criteria have been developed on humanitarian-related interventions. They are appropriateness, coverage, connectedness,
and coherence, and are considered as subcriteria to the five core criteria listed previously.¹⁸

In terms of timing, if an evaluation is intended to contribute to learning within the context of strengthening a selected intervention being piloted in a three-year project, then it may be prudent to plan for an evaluation midway through the project to allow for corrective action to be taken. If the intention is to extract lessons learned from a previous cycle of programming in preparation for a new one, then an evaluation might be strategically placed at the beginning of the new program cycle.

The Evaluation Matrix
The evaluation matrix is a tool that captures the evaluation plan in a matrix format. While there is no one standard, recommended evaluation matrix, Table 4 provides an example of the matrix and its contents.

Notes on how to complete the evaluation matrix:

**Column A:** This column helps you state your evaluation purpose. In stating the purpose, the fundamental consideration is use of the evaluation findings. The purpose should be an end and not a means.

**Column B:** Criteria are descriptions of the means by which evaluation purposes can be achieved. Stating the criteria helps focus and limit the number of evaluation questions. Criteria selection is, to a large extent, influenced by the intended use of the evaluation findings. Other considerations in selecting criteria include prior experience in conducting evaluations, examples from similar evaluations and advice from evaluation experts. This helps ensure the evaluation remains feasible.

**Column C:** Evaluation questions help determine the kind of information required for the evaluation. While it is possible to ask a myriad of questions for any evaluation, this may not prove useful or practical for the evaluation. To ensure focus, clarity, and conciseness, evaluation questions should be asked in the context of the criteria that have been chosen.

**Column D:** The common practice in many organizations is to list methodologies for data collection, such as surveys, interviews, etc. At this stage of the planning process, it is sufficient to state broad sources such as monitoring data (i.e., program reports), evaluation reports, and research. Details about how data will be collected will be provided in the inception report that will be handed in by the evaluation team. An “evaluability” exercise will help determine the appropriate methods for data collection.

**Column E:** This section is intended to show understanding of the dynamics of the program in its totality. Stating the timing of an evaluation in the context of the program cycle helps to address start-up, mid-, and end-of-program issues. It also brings into focus considerations of the purpose and choice of criteria for the evaluation.

**Column F:** The person responsible for an evaluation is the manager for the evaluation. This is different from the team that will conduct the evaluation and submit an evaluation report. The tendency here is to list the consultants or researchers in this column. The evaluation manager is the focal person who will ensure that the organization is reminded about the evaluation exercise when it is due. He/she will be responsible for ensuring that the steps for preparing and conducting the evaluation are adhered to and that they yield the desired result. The cost of the evaluation is computed based on several factors, including research costs (e.g., per diems, printing, equipment, supplies), dissemination activities, and others. The cost of an evaluation is influenced by several variables, including the complexity of the evaluation (internal vs. external, national vs. regional, etc.), availability of data, relative cost of hiring consultants (whether local or regional), and the cost of the evaluation as a proportion of the overall program budget. All these factors need to be considered when formulating an evaluation budget.¹⁹

Managing and Conducting an Evaluation

The following steps outline how an organization can prepare for and manage an evaluation, as well as how an evaluation team can go about conducting an evaluation.

Step One: Initial Considerations

As mentioned previously, deciding exactly why and when to conduct an evaluation is a process that begins at the program formulation stage. Program designers lay the groundwork for evaluation by ensuring that the program monitoring systems will be sufficiently robust. This allows for strategic information to be generated that will serve as the basis for asking critical questions about the effects of the HIV intervention being implemented.

Thought must be given to the involvement of stakeholders or partners in an evaluation. Stakeholder involvement enhances the credibility of the evaluation process and ensures increased acceptance of the findings. However, stakeholder involvement can be costly and time-consuming. It is advisable to conduct a stakeholder analysis early in the preparation phase to determine the different partners and interest groups that might be involved. If there is a need to involve stakeholders, they should be informed of their roles and anticipated responsibilities early on to allow for greater dialogue on the evaluation process.

Source: Adapted from UNDP.20
Evaluation utility is a critical consideration. Utilization-focused evaluation (U-FE) is based on the premise that evaluations should be judged according to their utility and actual use. During the evaluation process, the evaluation team should design the evaluation with careful consideration of how everything that is done, from beginning to end, will affect the intended use of the evaluation by intended users. In other words, the utility of an evaluation is judged by how real people in the real world apply the evaluation findings and experience the evaluation process.\textsuperscript{21}

Finally, planned program outputs and outcomes should be reviewed in the context of results from monitoring data to ensure that both are still relevant. It is advisable to review outputs and outcomes six months prior to the commencement of an evaluation as this will provide ample time to determine the relative worth of the evaluation based on monitoring data.

**Step Two: Preparation**

There are no hard and fast rules as to what preparatory tasks should be undertaken as these will depend on the complexity of the evaluation being undertaken. For instance, an evaluation of planning and implementation processes is not as complex as that of outcomes and impacts. Preparation is even simpler if the evaluation focal person or team has prior experience in conducting similar evaluations. Where outcomes and impacts are being evaluated, it is advisable to seek the services of expert evaluation consultants to guide the preparation phase. The following list outlines the stages of preparation:

1. Review selected intervention to be evaluated;
2. Formulate evaluation questions;
3. Assess “evaluability,” i.e., the extent to which the evaluation questions can be answered;
4. Develop an evaluation budget;
5. Formulate terms of reference (TORs);
6. Form an evaluation reference group;
7. Recruit an evaluation consulting team.

**Review selected intervention to be evaluated.**

It is important to examine the phases of the intervention (start-up, implementation, and closure or postproject, etc.) that will be addressed by the evaluation. This should be done within the context of the program intervention logic (i.e., conceptual, logical or results framework) and is made simpler when monitoring and reporting systems generate accurate and reliable program data and reports. An analysis of activities and outputs is essential to clearly establish what needs to be evaluated. If it is not clear what should be evaluated, it is advisable to postpone the evaluation until clarity has been achieved.

**Formulate evaluation questions.** Formulating evaluation questions is an iterative process that begins with an understanding of the scope and focus of the evaluation. Scope and focus are largely determined and defined by the program scope itself as detailed in the project document. However, the scope and focus of an evaluation are shaped by the selected criteria and standards. Selecting the criteria for evaluation and stipulating the standards to be used during the evaluation are a key step of any evaluation. With utilization as a major underlying theme, the number of questions that can be meaningfully addressed should be no more than what is practically required. Thought should be given to what information is required in order to meet the purpose of the evaluation. It is important to examine the various criteria that can be used after carefully considering the information requirements.

Reviewing evaluations that have been conducted elsewhere for similar interventions, in order to ascertain the questions that were asked and how these were arrived at, is also useful. For example, in Swaziland, Organization Y was planning to evaluate the first five-year phase of its program operations in readiness for the grant-writing process for the second five-year phase. In developing the evaluation questions for inclusion in the TOR, the M&E team from that organization reviewed similar past World
Bank evaluations of national projects for evaluation questions that were used and how bank evaluators had generated these questions. Three national evaluations were reviewed, and selected questions from these were adapted and used to formulate questions that were included in the TOR.

Assess “evaluability.” Evaluability is the extent to which the evaluation questions can or cannot be answered, thus helping to determine whether or not the evaluation is feasible. Through an evaluability assessment, modifications can be made to the evaluation and evaluations questions dropped if they are deemed too difficult or expensive to answer; new questions can also be introduced to add depth. To assess evaluability, program design factors, such as the program framework logic, should be reviewed and the availability and quality of baseline and monitoring data assessed. Often this is done during the earlier intervention review stage of the evaluation.

Develop an evaluation budget. Financial resources often significantly influence the occurrence and scope of an evaluation. The following general rules of thumb can help decide how to utilize scarce resources in order to yield the best possible outcome.

- If few resources are available, the first priority should be to establish a monitoring system. It is always advisable to set up an efficient monitoring system that can, at a minimum, demonstrate progress of implementation against stated objectives.
- If additional resources are available, some form of process evaluation can be undertaken.
- For an outcome or impact evaluation, even higher levels of financial and technical resources are required and should be planned for accordingly.

Available resources, regardless of how scarce or abundant, should be used creatively. For instance, the collection of information that is good to have but not overly important to the evaluation process should be limited. It is also important to know whether there are surveys being conducted by other groups in the same areas that may address some or all of the current areas of interest and whether they have yielded or will yield information of an acceptable quality. It is also useful to explore collaborations with other stakeholders so that resources needed for data collection can be pooled together.

Formulate terms of reference. The TORs for an evaluation team are a summary of the evaluation process that outlines all the previously mentioned preparatory steps. The TORs should include the purpose of and background for the evaluation, evaluation objectives and questions, deliverables, time frame, and required expertise and criteria for tender selection. In essence, they are a set of instructions for the evaluation team on how the evaluation should be conducted. Formulating TORs for an evaluation should be done well in advance of the evaluation to allow for stakeholder input. If an evaluation reference group exists, one of its early functions will be providing comments and input to the development of evaluation TORs.

Form an evaluation reference group. The evaluation reference group is mainly intended to serve in a quality assurance capacity and adds to the credibility of the evaluation over and above the use of external evaluators. The reference groups also acts as a check and balance to control any political biases on the part of the organization requesting the evaluation as well as the technical biases of the evaluators. Depending on the resources available, an evaluation reference group can range from two to six individuals. Appointing individuals to serve as reference group members should mirror the recruitment of evaluators, with similar criteria in regard to skill sets and qualifications.

Recruit an evaluation consulting team. Ideally, the evaluation team (external consultant team, in-house team, or a mix) should be composed of a variety of competencies capable of
STRENGTHENING THE USE OF EVALUATION FINDINGS

Traditionally, monitoring has been used effectively to serve the reporting needs of health-care organizations. However, reporting is not the same as using the findings arising from the analysis of monitoring data. Because most organizations are habitually accustomed to monitoring and reporting, evaluation has tended to follow a similar approach, wherein the focus is on reporting of findings rather than the use of those findings. The following are some practical suggestions for organizations that wish to strengthen their use of evaluation findings:

In any plan for monitoring and evaluation, ensure that resources for facilitating the use of findings have been indicated and allocated.

Deliberately set up or review structures for knowledge management and learning within the organization. Where an organization has an annual review or planning sessions and quarterly program meetings, emphasis should be placed on making sure that these structures facilitate learning and knowledge management. In preparation for such activities, the following questions should be asked:

During annual meetings, are there clear objectives that require your organization to apply lessons learned? Is documentation of program lessons arising out of analysis of program reports a requirement?

Does the organization have requirements in place for regular analysis of program data and reports for the purposes of improving program management? (Note that this requirement supersedes analysis for the purposes of reporting progress or a lack thereof.)

Are reporting processes aligned toward facilitating communication of implementation progress only? Or do they include a major component that requires the reporting agents to demonstrate/propose the use of findings through modeling and practical recommendations detailing the pros and cons of using the findings?

Create an organization-wide culture of inquiry by:

- extending an opportunity to others to work at problem solving by actively sharing skills and expertise with one another (i.e., “face-to-face” interaction without unnecessary dependence on information technology);
- unbinding knowledge from a single specific context in order to maximize knowledge transfer; for example, franchising is a well known business strategy for expanding operations in the private sector. Love Life (a South African National HIV/AIDS initiative for youth) successfully used the concept of franchising to establish what they call Love Life franchises (i.e., AIDS Service Organizations) that buy into and implement the Love Life brand. The difference in this case is that Love Life provides full funding for the establishment of the franchise as well as technical support whereas in the private sector, the interested part pays for the franchise.
- enabling others to recognize and respect what they already know as well as the knowledge that exists within their community;
- providing others with several examples of a new concept as well as fostering an understanding of how essential features of the concept are reflected in a range of
settings; For example, Prevention with Positives (PWP) is a relatively new concept that has come to the fore in many developing countries due to the proliferation of life-prolonging HIV treatment programs. In Botswana, PWP activities include setting up support groups, holding the annual Miss/Mr. Stigma free fairs, and the communication campaign—“It stops with me.”

- strengthening one’s own and others’ ability to judge when new knowledge should be used.

Step Three: Conducting the Evaluation Research
This step is characterized by the inception and monitoring/support phases of the evaluation research activities. During the inception phase, the evaluation team should submit a detailed proposal for the evaluation exercise, known as an inception report. The inception report should at a minimum contain an interpretation of the evaluation questions and how these have led to the chosen methodology for data collection and analysis, including an evaluation plan. The inception phase is also a time to make any needed changes to the TORs or amendments to the evaluation proposal. However, an inception report should not be used as a basis for further reviewing the suitability of individuals to carry out the evaluation. This should largely be determined during the recruiting stage.

During the research phase of the evaluation, communication and practical assistance are crucial to ensure minimal disruptions and successful completion of the research. Essentially, it is important to establish clear communication channels and state up front what assistance can be offered over and above what has been budgeted and planned for in the evaluation proposal, such as making of appointments, arranging of site visits and obtaining of permission from community “gatekeepers.”

Step Four: Dissemination of the Evaluation Report
An evaluation report is different from a research report. The former is intended to communicate to the users the evaluation results, their implications, and (where applicable) recommendations. Unlike a research report, few users of an evaluation report are interested in the detailed explanation of the evaluation process or the finer aspects of the defensibility of the research. These technicalities have already been dealt with at the inception phase. During the dissemination stage, the report that has been submitted is checked for completeness. It is advisable that this is done using an evaluation report review checklist (several of which are available on the Internet). Once the evaluation report has been accepted, it should be formally communicated to the evaluators and arrangements made for its dissemination. Depending on the intended users and uses of the evaluation, other means of dissemination, such as publication in a journal or submission to online evaluation interest group listings, can be considered.

Step Five: Use of the Evaluation Findings
Use doesn’t just happen naturally, but rather it needs to be facilitated. This implies that after the dissemination of findings, time and resources should be set...
aside for facilitating the actual use of the evaluation findings. There are two critical activities at this stage: modeling the use of the findings and working with users to implement the findings.

Modeling the use of evaluation findings requires a careful examination of the purpose for the evaluation, a review of any changes in the settings being looked at since the evaluation was conducted, and the involvement of new stakeholders or partners. This may require making presentations to various units or sectors on how the evaluation results can be used and their implications on current programming. The importance of dissemination activities as part of the evaluation process cannot be underestimated. Dissemination is more likely to occur if a line item for dissemination activities is included in the original evaluation budget.

While primary users may readily apply the results of the evaluation, there are capacity issues inherent in the application of findings that should be reviewed and addressed. These may include a needed change in skill sets, acquisition of new knowledge, or the implementation of new technologies. Careful consideration should be made for training to improve knowledge and skills or to orient users on the introduction of new technologies.

CONCLUSION
Monitoring and evaluation of HIV programs has progressed significantly since the early 1980s, moving from a purely bioclinical framework to a broader, multifaceted approach. Along the way, this practice has helped change the global understanding of the HIV epidemic and the responses to it. M&E also plays a crucial role in the efficient and effective implementation of projects and programs and in ensuring accountability. This chapter has highlighted some of the main M&E principles, frameworks, and methodologies currently in use. In addition, given that much of the HIV M&E efforts to date have paid insufficient attention to evaluation, the chapter has covered the basic evaluation concepts and the management of the evaluation process. The importance of integrating M&E activities into the overall design of HIV programs and the need to strengthen and expand the use of M&E has been emphasized.

The Third One in Practice: Monitoring and Evaluation of the Botswana National HIV Response

John Puvimanasinghe, Wayne Gill, and Eduard Beck

The Third One in Practice: Monitoring and Evaluation of the Botswana National HIV Response

T

his chapter highlights practical experiences with monitoring and evaluation (M&E) of Botswana’s national HIV response with a view to demonstrating the role of the “Third One” in harmonizing and coordinating sub-national, national, and global M&E systems. Botswana is currently moving toward the creation of one integrated country-level monitoring and evaluation system (i.e., the “Third One”). Although it still has some way to go toward achieving this goal, Botswana has gathered a great deal of practical experience in planning and implementing a national M&E system. It is hoped that the information culled from those experiences can be of use to other countries engaging in similar efforts. The chapter also includes a discussion of the country’s HIV epidemic and the national response, as well as a description of the various M&E structures and systems currently in place.

COUNTRY DESCRIPTION

Botswana is a landlocked country with a total land area of 582,000 square kilometers situated in southern Africa. The country is bordered by Zambia, the Republic of South Africa, Zimbabwe, and Namibia. Botswana’s population is roughly 1.7 million and represents one of the smallest populations of any African country. At the time of its independence in 1966, Botswana’s gross domestic product (GDP) per capita was one of the lowest in the world. Yet Botswana has experienced strong growth over the past three decades (with an average GDP growth rate of 6% per annum), and in 1993 ranked 71 out of 178 countries on the United Nations Development Program (UNDP) Human Development Index (HDI). Unfortunately, even with the state’s prioritization of economic growth, Botswana’s HDI rank fell to 114 out of 162 by 2001, mostly due to the severity of the country’s HIV epidemic.

THE EPIDEMIC AND ITS CONSEQUENCES

HIV was first discovered in Botswana in 1985. Since then, the virus has been spreading rapidly and taking an increasing toll, making Botswana one of the countries most affected by HIV. The 2004 Botswana
HIV/AIDS Impact Survey (BAIS II) showed a 17.1% HIV prevalence in the general population for people older than 18 months of age.3 According to the Ministry of Health’s (MOH) antenatal care (ANC) surveillance survey carried out in 2007, 33.7% of pregnant women in the country were HIV-positive.3 However, a declining trend in HIV prevalence among ANC attendees has been noted between 2001 and 2006. As shown in Figure 1, the largest decline between 2003 and 2006 was seen in the 15-to-19 and 20-to-24 age groups.

By the end of 2006, it was estimated that approximately 276,000 people were living with HIV in Botswana. That number is projected to reach 348,000 by the year 2019.4 The government’s central statistics office estimated that 18% of all reported deaths in Botswana in 2003 were attributed to HIV and AIDS. This sharp rise in mortality has caused life expectancy to fall, resulting in an overall reduction in the country’s population growth rate.

The epidemic has affected both urban centers and rural communities with equal intensity and has become a serious developmental and social problem, negatively affecting all sectors of society. The roll-out of antiretroviral therapy (ART) has made the disease more manageable, enabling a shift away from acute care toward a greater emphasis on chronic care. However, health systems have become inundated with HIV/AIDS patients, and subsequent pressure has been felt on all other sectors competing for both human and financial resources.

BOTSWANA’S NATIONAL RESPONSE
Strong commitment from the government of Botswana has enabled an unprecedented multisectoral response to the epidemic, with more than 5% of the national budget going toward the fight against HIV. Within the government, the Ministry of Health and the Ministry of Local Government
(MLG) are key players in the national response to the epidemic. The MOH has been tasked with planning and coordinating health care in the country and administers all hospitals, while the MLG oversees implementation of health care and administers the primary care clinics in the country. Through numerous targeted policies and legislative actions facilitating the rapid roll-out of prevention of mother-to-child transmission of HIV (PMTCT) and ART programs, Botswana has achieved nearly 90% national coverage of these services.

A number of treatment, care, and prevention programs have evolved as a response to the epidemic that fall within the MOH’s Department of HIV/AIDS Prevention and Care (DHAPC). As part of the national response, the government decided to make HIV/AIDS treatment one of its priorities in line with its “Vision 2016” goal of creating a healthy nation and the National Strategic Framework goal for the provision of treatment, care, and support. In 2002, the government initiated the national ART program (named MASA after the Setswana word for “a new dawn”), which offers free ART to citizens who meet eligibility criteria. Beginning in 2002 at the Infectious Disease Control Clinic at Princess Marina Referral Hospital in the capital city Gaborone, ART services were rapidly scaled up throughout the country. Currently, 32 ART sites are operational, each site comprising a hospital providing ART services and related satellite clinics within its population catchment area. As the ART program expanded, limited capacity within the public health sector was seen to hinder further scaling up of the program. In 2004, in light of the call for universal access to ART and building upon World Health Organization (WHO) recommendations, the ART program developed a model for partnership between the government and the private sector for the outsourcing of patients on ART from the public to the private sector. By the end of December 2007, 75,082 patients were receiving ART in Botswana’s public health sector, and a further 8,336 patients had been outsourced from the public sector to the private sector. As depicted in Figure 2, this increase in ART coverage has been associated with an overall reduction in adult mortality. The ART program is currently collaborating with MLG to scale up prescribing and dispensing of therapy at satellite clinics, facilitated by an innovative nurse care model that enables specially trained nurse practitioners to manage uncomplicated ART patients at the clinics.

Botswana established one of the first national PMTCT programs in Africa. The program was piloted in Gaborone and in the northern town of Francistown in April 1999, and rapid roll-out of the program was begun in July 2000. By November 2001, all 634 public health facilities throughout the 24 health districts in Botswana offered PMTCT. Of 8,287 new ANC clients who visited public facilities during the second quarter of 2007, 82% agreed to receive an HIV test, of which 28% were found to be HIV-positive. The Botswana National Strategic Framework for HIV/AIDS (2003–2009) calls for a reduction in the number of infants born to HIV-positive mothers who are infected by 18 months (from 21%–40%) in 2002 to 10% by 2009. Botswana appears well on its way to meeting this goal, according to a study in Francistown in 2006 that found a 6.7% rate of mother-to-child transmission of HIV.5,6

HIV testing serves as an entry point for utilization of other national response programs. The routine HIV testing and counseling (RHT) program (also known as provider-initiated testing and counseling) was initiated in Botswana in 2004 and is offered at all government health facilities across the country. According to the RHT protocol, all symptomatic patients with signs and symptoms that could be related to HIV/AIDS and all adults and adolescents
seen at health facilities are offered an HIV test and are tested in the absence of expressed refusal. RHT also incorporates voluntary counseling and testing (VCT) as one of its components. According to the 2007 fourth-quarter report of Botswana’s National AIDS Coordinating Agency, the actual uptake of RHT was greater than 90%, with 22.4% of those tested found to be HIV-positive. VCT is run by the private sector, and there are currently three service providers in this area. Tebelopele, the main provider of VCT in Botswana, has mounted an aggressive testing outreach campaign that includes the operation of temporary testing centers in low-income areas with the aim to reach more clients.

Other initiatives overseen by DHAPC and MLG include the Community Home-Based Care program, the Male Circumcision program and the Orphans and Vulnerable Children program. The country has also secured a safe blood supply.

**NATIONAL MONITORING AND EVALUATION FRAMEWORK**

In line with the “Three Ones,” Botswana has established one national HIV/AIDS coordinating body, one national strategic framework, and one national M&E system. Botswana’s National AIDS Coordinating Agency (NACA) was established in 1999 under the direction of MOH. In 2002, it was moved to the Ministry of State President in line with current thinking that HIV could no longer be seen strictly as a health problem but rather as a development challenge. The repositioning of NACA was instrumental in mobilizing a broad-based, multisectoral national response.

---

**Figure 2. Association between increasing ART uptake and decline in overall adult mortality, 2003 to 2005**

NACA was assigned the function of monitoring and evaluating the national HIV response to reflect the growing recognition of the role of M&E in development management. As a first step, an epidemiology unit was set up within NACA with a key mandate for M&E. The unit laid the foundation for the Botswana HIV/AIDS Response Information Management System (BHRIMS), a multilevel, multisectoral, national M&E system that has come to play a central role in NACA’s routine business processes.

At the same time, Botswana developed the National Strategic Framework 2003–2009, building on the experience gained from previous short-term plans. The National Strategic Framework recognized the critical role of M&E in strengthening the management of the multisectoral national HIV response to such a degree that BHRIMS was identified as the vehicle by which the country would “ensure accountability, appropriate policy formulation and review, program improvement, and social justice through the direction of resources to the most vulnerable groups.”

THE NATIONAL MONITORING AND EVALUATION SYSTEM: BOTSWANA HIV/AIDS RESPONSE INFORMATION MANAGEMENT SYSTEM

BHRIMS was developed out of the need, as stated by the National Strategic Framework, “to gain a better understanding of the HIV interventions in the country, generate adequate information on the response, and improve the utilization of generated information for program planning, policy formulation and appropriate allocation of available resources.” However, the implementation of BHRIMS posed many challenges—first, the objectives of BHRIMS needed to be clearly spelled out; second, the structure of BHRIMS needed to be conceptualized; and third, an implementation strategy had to be developed.

The original objectives of BHRIMS were to:

- establish a monitoring and evaluation infrastructure;
- support the storage and analysis of all available HIV/AIDS data at different levels in the country;
- improve the accessibility of HIV/AIDS information and data;
- increase the utilization of available reports and data for action; and
- maintain institutional memory of the HIV/AIDS national response.

In recent years, various versions of these objectives have emerged; however, there seems to be a general convergence in terms of what the system seeks to achieve—that is, the promotion of evidence-based program development and management by establishing a culture of systematic data collection, storage, processing, reporting, and dissemination.

The overall structure of BHRIMS resembles that of the national HIV response, since useful data are generated continuously within programs from the various sectors (Figure 3).

The following are some important features of the BHRIMS structure:

- It is multisectoral, which is consistent with the recognition that HIV is not just a public health challenge but a development issue as well—hence the need to enlist contributions from a wide variety of stakeholders.
- Feedback is emphasized. The bidirectional arrows symbolize the importance placed on information sharing, from community-level response upward, and back down again. This ensures that the system does not end up being a “conveyor belt” of data from generation points to the top, as this would likely lead to reporting fatigue and disempowerment of implementing partners.
• NACA is positioned as an information hub. It is where all reports end up before they are collated and reported to the National AIDS Council. As none of the sectors report directly to that council, this structure enables NACA to harmonize M&E systems and standardize reporting formats. This is a critical ingredient in establishing a single national M&E system, as it facilitates data collection that meets agreed-upon national information needs.

The BHRIMS Implementation Strategy

The BHRIMS implementation strategy involved the formation of a national BHRIMS Technical Working Group (TWG). Broadly, BHRIMS TWG is a forum that brings together both local M&E experts and critical program managers to strategize on the best options for M&E system development in Botswana. A number of projects have been successfully carried out through BHRIMS TWG, such as the national M&E capacity needs assessment, development and implementation of the national M&E curriculum, the population-based Botswana HIV/AIDS impact surveys (BAIS I and II), conducting of national HIV/AIDS and related sexually transmitted infections conferences, UNGASS reporting, and numerous others. To date, BHRIMS TWG meets quarterly to review progress reports from its four subcommittees: evaluations, informatics, harmonization, and research.

The four subcommittees are organs through which various projects related to the national M&E mandate are implemented. Broadly, the evaluations subcommittee coordinates all projects and program evaluations by providing technical guidance and ensuring quality throughout the evaluation process. It is also in the process of developing an evaluation agenda for the country. The informatics subcommittee oversees the information and communication technology (ICT) requirements needed for transforming BHRIMS from a paper-based to an electronic system, mainly by working with ICT service providers to deliver an effective and efficient electronic M&E system, known as

Figure 3. The structure of the Botswana National M&E System (BHRIMS)
The single biggest challenge faced by BHRIMS since its inception has been lack of capacity, both in the area of human resources and M&E skills. As one of its first activities, BHRIMS coordinators conducted an M&E capacity needs assessment in 2002, which highlighted an immense shortage of personnel. Although pockets of M&E practice were noted in the country, most staff were “part-time M&E and full-time something else.” This meant that M&E had no dedicated staff of its own, which by extension had implications for data collection, completeness, processing, reporting, and dissemination. Further, where staff were in place, they lacked basic skills such as computing, data management, data analysis, and working knowledge of basic M&E concepts. This reduced M&E activity to simple reporting, thus heightening the risk of reporting fatigue. Simply put, the systems in place were nothing more than data conveyor belts, from the bottom to the top.

However, BHRIMS has come a long way, and these challenges have been tackled with notable success. M&E officers/experts have been recruited at various levels of the system, most notably at the district level, where there are currently two M&E officers for each health district. All of these officers are university graduates, most with a social sciences background. It is expected that involvement of this cadre at the district level will improve monitoring at peripheral levels and data quality in general as they are closer to data generation points such as health facilities and project sites. Further, a national M&E curriculum was developed under BHRIMS in 2006, which is further discussed later in this chapter.

Another notable challenge is harmonization of M&E systems. It was never the intention of BHRIMS to set up a completely new system that ignored existing systems, despite the frequent isolation of those systems. Rather, the BHRIMS strategy is to interface with existing systems and complement them with additional substructures only when deemed necessary. The main advantage of this strategy is that it utilizes already-existing system momentum, thereby improving efficiency by injecting a few innovations as needed.

The biggest challenge lies in synchronizing the different systems, which until now have operated as silos, so that they serve multiple information needs without compromising quality. This calls for detailed mapping of stakeholders’ information requirements, prioritization and reprioritization of information needs, and, in some cases, reconciliation of definitions, among other activities. It could be argued that the success of the “Third One,” or one national M&E system, heavily depends on the extent to which various components of the main system are harmonized.
Another challenge for BHRIMS is the loss of institutional memory. Many members of the pioneer implementation team have since left the system for various destinations abroad. Most of those individuals are members of the development partner community who have been redeployed elsewhere. While their contribution has been immense, it would have been helpful for partners to be more flexible in terms of length of tenure for M&E officers at the country level. For instance, some of the officers left in the middle of critical projects in which they played instrumental roles. Such departures make it difficult to establish continuity and, by extension, sustainability within program activities. It has been found that mixing national and international technical expertise is worthwhile, not only for cross-pollination of ideas but also to avoid total collapse in the event that an international expert departs the country. Currently, most national staff circulate within various organizations in the country and as such are not lost to the system; in other words, there is no brain drain in the area of M&E in Botswana, as of yet.

Lessons Learned from the BHRIMS Implementation

After more than six years of implementation, BHRIMS has provided useful lessons that can help M&E system development in other settings. Here are some of the more important lessons:

- An M&E capacity needs assessment provides information for the development of a national system. It enables understanding of what is available, in what quantities and qualities, while also exposing existing gaps; it is the identification of such gaps that informs the development of the M&E plan.
- The creation of a forum where M&E issues are discussed is essential. Botswana has BHRIMS TWG for this purpose, which has functioned well over the years. Not only does such a forum
provide a meeting point where M&E personnel from various sectors can share ideas; it also provides an entry point for various collaborative efforts between national partners as well as between national and international partners. In short, the TWG enables effective coordination and harmonized implementation of M&E activities.

- Satisfying development partner and national HIV/AIDS response program needs can be challenging. Development partners tend to have M&E expertise in relative abundance. On the other hand, government, civil society, and the private sector are less well resourced in M&E, and thus depend considerably on development partners for technical input. This implies a lot of consultation and consensus building, which leads to slow development of the national M&E system. Some donors have found it difficult to resist the temptation to set up their own systems, parallel to the national one, thereby undermining, to a large extent, the development of the national system. This has been blamed on pressure to report to their principals. Although this challenge has no immediate solution, it highlights the need for realistic M&E plans and commitment to their implementation by all partners. The situation also calls for compromise—government and other national sectors need to understand the urgency development partners attach to their own reporting needs and should move at a reasonable pace to ensure that frustrations do not occur. More important, however, development partners need to appreciate that government is a large machine and inevitably takes time to mobilize. Any attempt to take shortcuts could lead to frustration on both sides. This is one area that requires joint planning between all partners involved in national M&E development.

**DECENTRALIZED (DISTRICT-LEVEL) MONITORING SYSTEMS IN BOTSWANA**

The Ministry of Local Government is a key player in the implementation of the National HIV/AIDS Strategic Framework. MLG oversees all national programs implemented by local authorities and coordinates central government activities at the district level through policy direction, capacity building, supervision, and social and community mobilization (to facilitate community participation in the development process).

The District Multi-Sectoral AIDS Committees (DMSACs) were established in 1997 with a mandate to coordinate HIV activities at the district and/or subdistrict level. In 2002, MLG began mainstreaming HIV into local government planning and delivery systems. This led to the establishment of an AIDS Coordinating Unit (ACU) within MLG, and four work streams were established under this unit. With this step, MLG, through ACU, became part of BHRIMS. The four work streams are as follows:

- Mainstreaming HIV into district development plans and urban development plans
- Integrating the Community Home-Based Care and the Orphans and Vulnerable Children programs as a continuum of care
- “Caring for Us” programs
- Monitoring and evaluation of district response

All community-based organizations and nongovernmental organizations report on their activities to the DMSAC on a quarterly basis through their representatives in the districts. The district AIDS coordinator (DAC) collects data from national programs using the relevant BHRIMS forms designed for the collection of data on the national HIV indicators. These are mainly output indicators linked to the National Strategic Framework goals. The DAC, as the secretariat to the DMSAC, collates, analyzes,
and reports the data on the district response to the DMSAC on a quarterly basis. This information is now sent to the central level on a quarterly basis, through the BHRIMS mechanism. Additionally, national response programs report directly to their responsible ministry, which is generally the MOH.

**Toward a Computerized District Data Collection System**

As part of enhancing monitoring and evaluation, MLG took steps to improve data quality as well as to enhance the user friendliness of the process used by the DMSACs for data collection, storage, use, and submission by moving from a paper-based to a computerized system. It was thought that such a system would not only enhance further data collection systems at the district level but also enable the DMSACs to conduct “on-the-spot” analyses of their own data.

The envisaged database was one that would be universal (i.e., could be used at all levels, including the district and national levels). It had to be user friendly and amenable for use in the monitoring of intended activities/projects. On the other hand, MLG recognized that the system ultimately had to be linked to the national M&E system (BHRIMS) and other national vertical systems. For that reason, the intended system had to demonstrate a high degree of compatibility with other databases.

With the assistance of NACA, the UNAIDS Country Response Information System (CRIS) software was identified in October 2005. That software provided a basic blueprint for the e-BHRIMS system as it met most of the user requirements. A district reporting functionality was built in and set the pace for the nationwide e-BHRIMS rollout in 2006. Currently, e-BHRIMS is installed in all of Botswana’s districts and subdistricts and at the MLG headquarters. In 2006, MOH identified the DHIS (District Health Information System) software to enable reporting from the district health teams. As CRIS uses the common XML data exchange format, it is possible to exchange data with other systems including DHIS, DevInfo, and KIDS mapping software. The data exchange function leverages the strengths of multiple systems and greatly progresses the mandate of the Third One.

**PROGRAM-SPECIFIC VERTICAL MONITORING SYSTEMS**

Apart from the national BHRIMS, many individual response programs in Botswana have their own vertical monitoring systems. These usually provide data for a larger number of indicators, which are required for individual program monitoring and management. These vertical systems vary from purely paper-based systems to more elaborate electronic systems and a data warehouse at the national level. The following example is a description of the monitoring system of the national ART program (MASA), which uses a combination of both paper-based and electronic systems.

**The MASA Program Monitoring System**

ART provision within Botswana was planned according to a site model. An ART site comprises a hospital supported by four satellite clinics. Initially, prescribing and dispensing of ART was limited to the 32 hospitals in the country due to the lack of previous experience with ART, concerns about creating widespread drug resistance, the expectation of an initially large cohort of critically ill patients requiring hospitalization, and the limited availability of resources. The role of the satellite clinics was to screen patients for eligibility and provide patient follow-up. However, in keeping with the goal of universal access to treatment, the roll-out of ART services envisaged that all satellite clinics would be capacitated to prescribe and dispense antiretroviral medications. As
of December 2007, more than 50 of the 128 satellite clinics in the country were prescribing and dispensing antiretrovirals.

Data are captured electronically into a Microsoft Access–based application (called the Patient Information Management System, or PIMS) at 28 of the 32 ART sites in Botswana, while a proprietary hospital information management system, the Integrated Patient Management System (IPMS), is in use at four ART sites. These applications produce a monthly report, the indicator definitions and format of which have been standardized throughout the country. The few satellite clinics with no computers produce this report manually. The paper-based aggregate data flow monthly from the satellite clinics to the respective ART site hospital, where the data are collated for the respective ART site. This aggregated ART site report is then transferred to the M&E unit of DHACP within MOH. Monthly patient updates are produced by the M&E unit, which also provides feedback to the ART sites (Figure 4).

Patient-level data from ART sites are also obtained at the M&E unit, which enables more extensive data analysis. However, as most ART sites are not linked electronically to the central level, de-identified patient-level data are transferred on a quarterly basis from the facilities to the central level on portable flash (USB) drives.

In Botswana, there is a need to integrate all data from the ART sites, including from ART pharmacies and laboratories, and also data from tuberculosis, PMTCT, and other programs, in order to create a longitudinal and comprehensive view of a patient’s record. This is a formidable task given that the data are scattered all over the country in separate systems (for each program) or on numerous stand-alone systems (e.g., those for ART clinics). Tools are also required to analyze these data across the various programs. MOH in Botswana is currently developing a data warehouse to support these requirements.
CONCLUSION
Throughout this chapter we have seen examples and practical applications of the ways in which the drive toward one M&E system, or the Third One, can begin to harmonize and coordinate district, country, and global M&E systems. In Botswana, we have been successful in encapsulating the divergent needs of all stakeholders that are involved in measuring the effectiveness of the national response to HIV.

Many challenges have been addressed through this effort, which has resulted in the prioritization of M&E as evidenced by increased funding and the creation of a multitude of tools (e.g., frameworks, guidelines, standards, systems, M&E plans, M&E curricula, and trainings). However, many factors continue to prevent us from having a clearer understanding of the epidemic and from adequately measuring the response. Capacity constraints relating to adequate numbers of qualified personnel continue to be a major inhibitor and restrict the growth of M&E.

In our ongoing pursuit of the Third One it will be critical to consider and absorb the lessons learned from previous years. One such lesson is that our constant and sustained emphasis on monitoring has been extremely detrimental to progress on the evaluation front. Limited focus on the “E” of M&E has restricted our knowledge of program effectiveness and, in particular, our ability to measure the success of prevention efforts. However, more recently NACA has spearheaded the development of a National Evaluation Agenda identifying eight critical questions highlighting evaluation foci. The next phase of implementation of these questions will address outstanding issues that have surfaced through the routine BHRIMS. Guidelines for this process are currently being developed and will be made available.

Another challenge that has besieged the M&E field is the utilization of information. Much of the information that we have gleaned sits on the shelves of our offices or in some long forgotten database. Ultimately, it is the timely and appropriate use of information that will transform policies and programs and ultimately improve the quality of life of our people.
REFERENCE LIST

Clinical guidelines provide recommendations to assist practitioners in providing appropriate health care based on scientifically valid research. Since the 1980s, the World Health Organization (WHO) has promoted the development and use of clinical guidelines to define standards and broad treatment protocols for the effective delivery of health services. This is ideally done through an evidence-informed approach that incorporates technological and biomedical advances. In resource-limited countries, guidelines have been widely disseminated to address the management of health conditions accountable for high rates of morbidity and mortality. The introduction of new health interventions or expansion of services to the provincial or national scale has also spurred ministries of health in these settings to draft or revise national guidelines, usually adapted from WHO documents, to provide clinical and operational guidance to health-care workers. This trend is evident in the recent and ongoing efforts to enhance access to comprehensive HIV care, including antiretroviral therapy (ART).

At the level of service delivery, however, national clinical guidelines lack the necessary specificity and ease of use to adequately guide health-care workers in the day-to-day practices that promote safe and effective patient care. At all levels of care in resource-limited settings, health-care workers have had limited experience in providing HIV care, particularly ART. The challenges inherent in the rapid start-up and expansion of comprehensive HIV care at health facilities underscore the value of written procedures, based on national guidelines, which provide a detailed description of processes or steps in organizing HIV-related services and performing clinical practices. Standard operating procedures (SOPs) facilitate comprehension of technical information related to HIV care and treatment and maintain consistency in its application in daily practice. This chapter explores the role of SOPs in standardizing and promoting the effective organization and delivery of HIV services at health facilities in resource-limited settings; it also presents case studies from Tanzania and Nigeria that describe experiences and lessons learned in developing and using SOPs to optimize quality HIV care.

SOPs for HIV Care and Treatment

Building the capacity of the health sector to provide state-of-the-science HIV care in resource-limited settings entails interventions in numerous...
areas of service delivery, including staff training, infrastructure upgrading, drug and commodity management, laboratory expertise, and health information management systems. SOPs in these service areas have several objectives. First, they provide managerial and clinical staff with operational information on organizing services within the health facility and how these services relate to one another in providing patient care. One example of this is the step-by-step process describing how a counseling and testing service directs a patient who is newly diagnosed as HIV-positive to the appropriate HIV care services. Second, SOPs clarify the roles and responsibilities inherent in delivering new HIV-related interventions so that managers and health-care workers understand what personnel, timelines, methods, and materials and/or equipment are needed to effectively provide care and minimize inefficiencies.

Third, SOPs describe processes for linking with community-based HIV services, such as home-based care and support groups for people living with HIV, which are essential components in the delivery and sustainability of comprehensive HIV care. To optimize a patient’s access to community-based services, SOPs can direct health facility staff regarding the steps for conducting an effective referral within a given setting or catchment area.

Fourth, SOPs provide instructions and describe the steps followed in performing specific clinical tasks or practices to support standardization, correctness, and effectiveness of performance. For example, a clinician conducts a baseline assessment of a patient who has newly registered at the HIV service. Since this assessment includes laboratory investigations as detailed in the SOPs, the clinician refers the patient’s blood specimen to the laboratory, which can then perform these tests in accordance with the laboratory SOPs. Following a standardized process for all new patients enhances the delivery of the best care practices by ensuring that clinicians follow explicit directions based upon national/international standards and that patient outcomes can be evaluated in terms of these instructions.

The SOPs that are developed for each health facility level detail procedures in a manner that complies with each facility’s standards as well as national guidelines. SOPs assist in optimizing care while taking into account the resources and capacities available at each level of the health sector. For practices performed at multiple levels, patient outcomes at each level are expected to be the same. Thus, the baseline assessment to determine eligibility to start ART in accordance with the country’s national ART guidelines should entail the same practices whether it is performed at a primary health center or a tertiary-level facility. When services are not within the scope of practice of a health facility at a particular level of care, or resources are not available at a particular site (e.g., lack of laboratory capacity to perform required baseline tests), SOPs guide health-care workers in referring patients so that they may access the same range of services.

SOPs are also instrumental in preparing new staff for HIV service delivery and in reinforcing standards and processes for existing staff who need additional training. For example, a pharmacy technician with no prior HIV experience who is newly deployed to an HIV care and treatment facility will benefit from the detailed processes described in the SOPs (e.g., counseling for and dispensing of antiretrovirals [ARVs], drugs for opportunistic infection [OI] prophylaxis and treatment). While the technician may have completed classroom training about various drugs, including all aspects of managing the supply chain (forecasting, ordering, stocking, recording, etc.), SOPs provide a readily available resource to guide practice in the pharmacy setting. This is the case both for inexperienced staff needing detailed information about drugs or procedures
and for experienced staff needing a reminder about a specific drug or procedure.

Finally, SOPs are a mechanism for evaluating service delivery. They can serve as a checklist for supervisors in monitoring job performance and can also help in coaching staff to improve clinical practices. For example, a records department manager who observes medical records left unattended on the registration desk in view of patients can utilize SOPs for the management of medical records and safeguards for patient confidentiality to reinforce correct and consistent job performance. As a result, staff learn how to improve performance and thereby render a higher quality of care in accordance with health facility standards and national guidelines.

National clinical guidelines do not take into account the varying operational and administrative environments in which health care is delivered. Guidelines for monitoring patients on ART, for example, are the same whether the patients are managed at a tertiary-level hospital or a primary care facility. However, the modalities and resources used for program monitoring tend to vary and are based on the cadre of available staff, the drug-prescribing authority of the staff, the laboratory and pharmacy infrastructure and capacity, and other features at each level of care. SOPs are designed to address these variations and guide practice that is appropriate to the particular operational context and capacity of the health-care site. This contributes to standardizing the delivery of care so that patients, whether in urban, peri-urban, or rural settings, at a community health center, or at a large specialty hospital, have a higher probability of receiving quality care in accordance with national guidelines.

The multiple concurrent initiatives to expand the availability of HIV care and ART in resource-limited countries (e.g., WHO’s “3 by 5”; the U.S. President’s Emergency Plan for AIDS Relief; the Global Fund to Fight AIDS, Tuberculosis and Malaria) have generated tremendous momentum for the extensive and rapid scale-up of HIV-related services. Large numbers of health-care workers and lay counselors have been trained in HIV management through short formal courses. Yet numerous challenges impact the actual delivery of care in the clinical setting. This is particularly true at the district and primary levels, where a limited number of trained staff, who are already overburdened with heavy patient loads and limited infrastructural resources, face increasing numbers of patients seeking care and ART. With broader availability of ART, the management of HIV as a chronic disease has become a reality. Yet this reality is a daunting one, given the dearth of health-care workers, the large population of HIV-infected patients, and the prevailing orientation of health services toward acute disease management.

SOPs facilitate delivery of HIV care in day-to-day practice by clarifying each health-care worker’s respective areas of responsibility; by detailing the specific steps involved in conducting procedures appropriate to these areas of responsibility; by recording the specific supplies, equipment, and commodities required to perform these procedures; and by describing the linkages and referral procedures between different interfacility services (as well as between facility-based and community-based services) to promote comprehensive HIV care. New models of care delivery are also emerging in response to present challenges, such as nurse prescription of ART at the primary health level. SOPs are a practical tool for standardizing these evolving practices and guiding health-care workers in performing new tasks in a manner that optimizes patient safety and positive care outcomes.

Further impacting delivery of HIV care is the dynamic and constantly evolving science of HIV/AIDS. SOPs that are revised to include new information provide a viable way for overburdened health-care workers to deliver care based on the most current and available scientific knowledge.
The organization and design of SOPs are key to achieving optimal efficacy in the clinical setting. SOPs typically describe clinical procedures and tasks in a sequential, step-by-step format. The appropriate cadre of health-care workers for the performance of each task is defined, and minimum equipment and supplies are described. The needed documentation of the services delivered is also explained. For clinicians who have limited experience in HIV care and who manage large numbers of patients on a daily basis, SOPs that contain these elements and are clearly and concisely written facilitate rapid comprehension and application to practice.

In addition to a written compilation of procedures, SOPs that are formatted as job aids provide a quick visual reference for health-care workers in busy clinical settings. Material aids such as wall posters and laminated pocket cards can detail procedural content succinctly and thereby serve as valuable memory cues for rapid decision making.

As SOPs and accompanying job aids are introduced at a facility, health-care staff should be oriented on these new tools so that they understand their benefits and accept them for use in their everyday practice.

The process of developing SOPs for HIV care ideally includes staff from the cadres who will be the end users. In cases where no SOPs currently exist, a national-level effort, led by the ministry of health (MOH) or another governmental agency, is required to define the objectives and topics of generic SOPs for HIV-related services and to ensure participation of health-care workers and local clinical experts in their development. International partners supporting the scale-up of HIV services in the country may participate by providing technical assistance. One possible approach is to convene a task force comprised of HIV-experienced health-care workers, MOH staff, and, when appropriate, international partners to draft the SOPs using national guidelines for HIV and ART patient management as a framework. SOPs used in other settings may also be reviewed for guidance and possible adaptation. These resources—HIV clinical experts and national HIV guidelines as well as international HIV guidelines—are primary sources for identifying the specific topics to be covered in the SOPs.

The draft SOPs are then field tested in a representative sample of health facilities for a defined period of time to determine their utility for clinical practice and to conduct a performance assessment of staff and orientation of new staff. Task force members meet with health-care workers and facility managers at each site, using the draft SOPs to gather feedback, including recommendations about the content, language, and other specific aspects of the SOPs.

At the health facility level, generic SOPs are adapted for use at each particular site, incorporating both the HIV-related services currently offered and those planned for the future. The process of adaptation will be defined by the setting, but may mirror the national-level process through the formation of a team comprised of health-care workers delivering HIV services, facility managers, and provincial or district-level health authorities. Site capacities and resources will impact the content of the SOPs; for example, when specific services cannot be provided on-site (e.g., management of ART patients who are failing first-line drug regimens), alternative procedures will need to be defined (e.g., referral to the closest health facility with capacity to manage treatment failure).

It is particularly challenging to ensure that SOPs in resource-limited settings continue to keep up with new scientific knowledge and changing clinical practices in HIV care and treatment. A standardized process is required to ensure that the latest information is available to providers at the health facility level in a manner that facilitates
integration into clinical practices. At both the national and health facility level, the procedure for reviewing SOPs on a regular basis and revising them as needed must be defined.

CASE STUDIES
The following case studies describe the processes by which two countries, Tanzania and Nigeria, have introduced SOPs as a strategy for building health-care worker capacity and standardizing delivery of HIV care and treatment. In both countries, initiatives were aimed at providing a practical and useful mechanism that could assist health-care workers in effectively delivering quality health-care services to the rapidly growing numbers of people seeking HIV care, including ART.

Tanzania
In Tanzania, preparing district-level hospitals for the provision of HIV care and treatment is a cornerstone of the national strategy to expand ART access. In April 2005, the national guidelines for the comprehensive management of HIV/AIDS were revised in accordance with international standards by the National AIDS Control Program (NACP), in collaboration with international partners, in order to build health-sector capacity for HIV services including ART. As of May 2007, 2,990 health-care workers, including clinicians, nurses, and pharmacy and laboratory staff, have been trained in HIV care and ART. Infrastructure has been renovated at over 200 district-level facilities to accommodate the high volume of patients seeking outpatient HIV care and to improve the flow of these patients between essential services (e.g., counseling and testing, prevention of mother-to-child transmission, TB, pharmacy). In addition, health information systems have been standardized to strengthen documentation, analysis, and reporting.

Treatment scale-up has been particularly challenging at the district level, where facility staff who lack previous ART experience are overburdened by the scarcity of clinicians and increasing numbers of patients seeking care and treatment close to their residence. The development of SOPs was identified as a key strategy to rapidly build these workers’ capacity and confidence in providing safe and effective HIV care.

In August 2005, the NACP, with technical assistance from Family Health International (FHI), prepared a protocol for the development of SOPs for HIV clinical care. The protocol called for the SOPs to be adapted from the national guidelines and stipulated that they include a comprehensive range of facility-based services, including the organization of HIV service delivery; referrals between facility-based services to optimize patient access; HIV clinical care for adults and children (including OI prophylaxis and management and other HIV-related conditions, palliative care, and ART); pharmacy dispensing of ARV drugs; laboratory monitoring schedules; HIV post-exposure prophylaxis (PEP); health management information systems; and referrals between facility services and community-based services, such as home-based care. The following standardized format for the drafting of SOPs was developed to ensure consistency: (1) the purpose of the SOP, (2) the responsible person, (3) required equipment and supplies, and (4) step-by-step instructions or description of the procedure. To optimize clarity and ease of understanding, it was suggested that the language be concise and action-oriented.

To draft the SOPs, the NACP and FHI paired a nurse based at the Dar es Salaam City Council Diagnostic and Nursing Services, who had extensive clinical and administrative experience in Tanzania’s health sector, together with an HIV nurse specialist working at FHI’s Institute for HIV/AIDS. The pair was briefed about the initiative by the director of the NACP, the head of the Care and Treatment Unit of the NACP, the WHO.
representative in Tanzania, and the FHI country
director in Tanzania. The pair then visited second-
ary and tertiary health facilities in two regions,
Iringa and Dar es Salaam, to obtain input from
staff, particularly regarding bottlenecks in service
delivery and constraints affecting quality of care.
They also observed clinical practices and the flow
of patients between services as well as linkages with
community-based services.

The initial version of the SOPs, drafted in
accordance with the established protocol, was
completed in December 2005. The draft doc-
ument was then circulated to a broad range of indi-
viduals and organizations in Tanzania for review,
including the NACP, international partners, and
select health facility staff, and revisions were sub-
sequently made based on the feedback. This review
process has been time-consuming and frequently
delayed by competing demands for the reviewers’
attention. The slow progress, however, reflects an
overarching commitment to forge agreement on
the methodology and content of the SOPs and gen-
erate wide-scale acceptance for their adoption.

In accordance with the original protocol, the
SOPs will be field tested at district and tertiary
health facilities when the revised version has been
approved by the NACP. Field testing is essential
for determining the usefulness of the SOPs in
the clinical setting and for generating ownership
among health-care workers, facility managers, and
district and regional health supervisors. The SOPs
are expected to provide essential guidance for sup-
portive supervision visits conducted by regional
health supervisors to monitor the compliance of
health facilities with criteria for accreditation as
ART delivery sites.

While the draft SOPs were being reviewed, the
FHI Country Office worked with the NACP and the
Clinton Foundation to adapt key content from the
SOPs into job aids. These aids were developed to
provide clinical staff with ready access to essential
information about the prescription of and adher-
ence to ARV drugs. Developed as wall posters and
as smaller desk charts, the job aids are proving to
be useful both for staff who have limited experi-
ence delivering ART and for busy experienced staff
who benefit from reminders. To date, the following
job aids have been developed and are in use at the
comprehensive HIV Care and Treatment Centers
(CTCs) established at regional-level hospitals:
- ART regimens used in Tanzania (first-line and
  second-line)
- ARV drug dosage schedules
- ART adherence checklist
- Directory of HIV-related services in the region,
  including home-based care services

After the field testing and finalization of the
SOPs, the next steps planned in Tanzania are the
dissemination of the SOPs to all district and tertiary
health facilities currently delivering HIV care and
treatment and the training of health-care workers
on the SOPs. Another initiative will be the adap-
tation of the SOPs for use at the primary health-
care level. Health facilities that begin offering HIV
services in the future will receive SOPs for their
level of care as well as staff training. Additional job
aids based on the SOPs will be developed by part-
ners such as FHI, working in collaboration with
NACP, as health-care workers and managers iden-
tify the need for tools to enhance the quality of care
delivery.

The experience in Tanzania has highlighted the
importance of the commitment and active partici-
pation of the NACP, the national agency tasked
with HIV/AIDS policy and service delivery. This
level of participation is essential to the development
of SOPs for HIV clinical care. Another important
element is the involvement of health facility staff
in the review of draft SOPs to ensure that they
are appropriate to local conditions. The presenta-
ion and formatting of content also impact usage
and service delivery; in Tanzania, the availability
of SOPs that clearly and concisely describe clinical practices, and job aids that summarize their essential content, is helping to guide health-care workers in the provision of safe and effective HIV care and treatment services despite their limited experience.

Completing the SOPs for facility use, however, has taken a prolonged period of time. Over a year has been spent on the review of draft procedures and subsequent revisions, primarily because the protocol seeks to involve the widest possible range of individuals and organizations during this stage. To date, no process has been defined for rapidly updating the SOPs based on new scientific evidence and revised national guidelines. This need must be addressed to ensure the delivery of HIV care and treatment services that are consistent with updated national and international standards of care.

**Nigeria**

In 2005, Nigeria had an estimated four million people living with HIV, with over 600,000 requiring ART. Despite this, only 45,000 had access to treatment. Until 2005, ART services were available only at tertiary health facilities, limiting access for large segments of the population. There was an urgent need to establish and scale up ART services, particularly at secondary-level facilities. The government of Nigeria, in collaboration with international partners, led a vigorous response, which included the drafting of national guidelines for HIV management, including ART, in 2003, with subsequent revisions in 2005 and 2007 to incorporate new scientific findings. An extensive effort was launched to train health-care workers, including physicians, nurses, and laboratory and pharmacy staff, particularly at tertiary and secondary levels. Key interventions to strengthen the health information systems for HIV care and treatment included the development of standardized data collection and reporting instruments, intensive training of facility-based medical records staff, and the pilot computerization of HIV-related clinic-based data. As of June 2007, infrastructure upgrades and other preparations for the delivery of HIV care, including ART, were completed at 210 sites throughout the country.

As part of this initiative, the Global HIV/AIDS Initiative Nigeria (GHAIN) project, funded by the U.S. President’s Emergency Plan for AIDS Relief and managed by FHI, in collaboration with the government of Nigeria, designated eight secondary facilities in six states for the provision of ART services in the first phase of a rapid scale-up process. However, no SOPs were available for HIV care and treatment at this level of health-care delivery. Moreover, the existing national ART guidelines were directed primarily at tertiary levels of care. It was therefore necessary to work with national health authorities to ensure that the national guidelines and related SOPs were made appropriate for use at the secondary level.

To address the need for revision of the national ART guidelines, HIV-experienced clinicians with the FHI/GHAIN project made the case for the expansion of the guidelines to include settings beyond the tertiary care level to key Nigerian health authorities, including the National AIDS and STI Control Program (NASCP) in the Federal Ministry of Health (FMoH) and the National AIDS Control Agency (NACA). With a favorable response from the FMoH and NACA, the FHI/GHAIN staff collaborated with the health authorities and representatives from other HIV program implementers in Nigeria to update and adapt the national guidelines. The revised guidelines are currently being disseminated throughout Nigeria.

Simultaneous to the revision of the national ART guidelines, staff from the Clinical Services, Pharmacy, and Monitoring and Evaluation Departments of the GHAIN project began drafting procedures for ART service delivery to
expedite their availability for health facility use. Generic SOPs for ART developed by FHI were used as a starting point and were subsequently reviewed and adapted for the Nigerian health sector context and, specifically, the secondary level of care. The draft was reviewed by clinicians from FHI’s Institute for HIV/AIDS in Arlington, Virginia, and following their revisions was presented by the FHI/GHAIN team at a stakeholders’ meeting convened by the FMOH/NASCP and attended by representatives from the FMOH and staff from select secondary health facilities. During the three-day review meeting, participants worked in groups to review various components of the SOPs. The groups then presented recommendations in plenary sessions, and a final draft was produced.

The SOPs were field tested at the six secondary health facilities that had recently initiated ART interventions with FHI/GHAIN support in accordance with the protocol developed during the stakeholders’ meeting. Health-care workers in the ART delivery unit (referred to as the HIV Comprehensive Care Center), the pharmacy, the laboratory, and the records department, as well as managerial staff at each facility, were oriented on the SOPs. During the piloting, which was conducted for a period of six months, FHI/GHAIN clinical and monitoring and evaluation staff conducted twice-monthly visits to the sites to mentor staff and generate feedback on utilization of the SOPs. Key recommendations from facility staff centered on clarifying text and developing job aids to facilitate integration of the SOPs into clinical practice.

At the end of the field testing, FHI/GHAIN incorporated the recommendations from the health facility sites into the draft and circulated the finalized SOPs for the secondary level to the FMOH/NASCP, NACA, and the six health facilities where ART had been integrated into service delivery. Job aids developed based upon health-care worker requests included the following:

- First-line and second-line ART regimens used in Nigeria
- Adult and pediatric ARV drug dosages
- ARV adherence education and counseling flowchart

Since this initial phase of SOP development and testing, FHI/GHAIN has monitored compliance with the SOPs by conducting regular visits at the facility sites using a standardized tool developed by the GHAIN Monitoring and Evaluation Department. At the end of each visit, findings are reviewed with clinical and managerial staff and any challenges reported by health-care staff in the use of the SOPs are discussed. The monitoring visits have revealed a sustained high level of compliance with the SOPs at the FHI/GHAIN-supported sites. From the perspective of facility staff, health-care workers have reported that, particularly during the early phase of treatment delivery where there has been no prior experience with ART, the SOPs provide useful guidance regarding the steps for initiating treatment, drug dosages, drug side effects and their management, adherence assessment, and patient-monitoring scheduling, including specific laboratory testing requirements. Over time, however, they report that the increasing patient load is creating challenges in adhering to the SOPs and providing quality care.

In January 2007, after a year of SOP utilization by the six health facilities, a second stakeholders’ meeting was organized by the FMOH/NASCP to produce national SOPs for ART delivery at the secondary level. It was attended by FHI/GHAIN, U.S. government implementing partners, and other HIV-service-delivery organizations including advocacy groups for people living with HIV and health facility representatives. The national SOPs, drawn almost entirely from those developed by FHI/GHAIN and used at the six secondary
facilities that were the focal sites for Nigeria’s initiative to expand treatment at this level of care, are being finalized for dissemination as ART is being rapidly introduced into an increasing number of secondary health facilities throughout the country.

While FHI/GHAIN’s role in drafting the SOPs expedited their actual production, the close collaboration with health-care workers at the GHAIN-supported secondary-level facilities was instrumental in ensuring the relevance of the content and the ultimate acceptability of the SOPs for use in clinical practice. The stakeholders’ meeting convened by the FMOH/NASCP was an efficient process for the detailed review of the draft SOPs. As in Tanzania, the process for the ongoing review and updating of SOPs remains undetermined. This issue needs to be addressed, as the rapid expansion of HIV care and treatment in Nigeria is expected to impact quality of service delivery.

LESSONS LEARNED AND ONGOING CHALLENGES

Several insights have emerged from the initiatives to incorporate SOPs into HIV health-care delivery in Tanzania and Nigeria. For instance, HIV/AIDS care including ART is a dynamic, rapidly changing field in terms of science and health-care delivery practice. International and national guidelines need regular updating to reflect advances in knowledge and clinical practices, as do the SOPs that are based upon these guidelines. A protocol for updating SOPs is needed that defines who is responsible for the process (including funding sources), when it will occur (e.g., whenever international and national guidelines are revised), and how the revised version will be disseminated to health facilities throughout the country.

Another area requiring further thought concerns the use of SOPs as a mechanism for continuously promoting quality of care at the health facility level. Will district or regional health authorities conduct regular supervision of HIV-service delivery using a standardized instrument based upon the SOPs used at the facility? How will facility-based supervisors and managers use the SOPs for evaluating staff performance and determining whether services are being provided in accordance with the SOPs? Can a process of quality improvement be institutionalized at health facility sites whereby health-care workers draw upon the SOPs to self-evaluate their practices and the outcomes of the health care they provide, and take appropriate measures to enhance the care they deliver?

Finally, targeted evaluations are essential for gaining understanding of the initiatives where SOPs for HIV care and treatment have been introduced in resource-limited settings to date, such as Tanzania and Nigeria. An important area of inquiry is the utilization of SOPs by health-care workers and their perception of the benefit to clinical practice. Another need is to measure the impact of SOPs upon clinical services delivery. For example, is the length of time clients wait for consultation affected by adherence to SOPs for registration, triage, and other aspects of patient management? Is accurate drug prescription associated with the use of SOPs and their related job aids? Are health-care workers more or less likely to conduct ART adherence counseling at each client visit if they follow the SOPs that designate the responsible staff for this role and the schedule for conducting this activity?

CONCLUSION

There are undoubtedly a number of areas related to the implementation of SOPs that need to be explored and improved. Despite these challenges, SOPs constitute an important component of efforts to scale up HIV care and treatment in resource-limited settings and help standardize the application of national guidelines and international practice standards for HIV patient management in varying operational and administrative contexts.

QUALITY MANAGEMENT OFFERS providers a standardized approach for addressing the appropriateness of care that can be applied in even the most resource-limited settings. The integration of quality into current efforts to provide and expand HIV care in resource-limited settings is an area of active work and investigation.

Implementing a quality-management program in a resource-limited setting involves the balancing of a number of factors, including working to measure and improve quality as soon as possible, dealing with competing demands in the absence of abundant resources, and building site-level capacity to participate in this work. In this chapter we provide an overview of quality management as an integrated approach to measuring and improving quality within the context of HIV/AIDS program scale-up.

There is some limited information in published literature on the use of different approaches to quality management and improvement in resource-limited settings.\textsuperscript{1-4} Øvretveit describes a number of approaches to improving the quality of health services in developing countries, including strengthening management, health-care reorganization, and adapting and applying quality improvement (QI) methods.\textsuperscript{1} Other approaches include quality measurement and standards (such as accreditation), engagement of teams to work on specific problems using QI methods, and community and patient participation.

The overall approach for quality improvement discussed in this chapter is based in part on the HIVQUAL framework of quality management (developed by the New York State Department of Health AIDS Institute and the Health Resources and Services Administration), which has been implemented in Thailand\textsuperscript{5, 6} as well as in a growing number of countries in sub-Saharan Africa\textsuperscript{7} (also B. Agins, MD, MPH, personal communication, July 2007). The discussion will also draw from a range of experiences in other settings. The focus will be on three core activities: measuring performance, improving quality, and building capacity and infrastructure. These activities will be discussed as they pertain to quality management at both the site and higher (i.e., program, district) levels. While QI work is of particular relevance to clinical leaders and management at the site, district, and program levels, it’s also important for supporting partners working to help ensure that quality care is provided to all those in need.
INTRODUCTION TO QUALITY AND QUALITY MANAGEMENT

The Institute of Medicine defines quality in health care as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.” In practice, quality can be defined as the degree to which a health or social service meets or exceeds established professional standards and user expectations and achieves desired outcomes. Although patient and provider characteristics and behaviors play a central role in determining whether desired outcomes are realized, the service-delivery system and organizational context in which care is delivered contribute equally to whether quality of care is achieved.

Quality management consists of the set of coordinated activities and infrastructure within an organization designed to support the activities that address the quality of care provided. The goal of quality management is to define, measure, and improve quality of care so that the desired outcomes are achieved according to accepted standards. These activities are part of the essential framework for a systematic approach to performance measurement and quality improvement. Quality management should be integrated into the planning and implementation of care and treatment programs in order for it to be carried out successfully.

Quality improvement processes address identified gaps in performance and assist in improving care to produce more consistent outcomes. Improvements are achieved through repeated cycles of testing changes to the system, measuring the impact, and then adapting or expanding the changes based on the results. Ideally, QI efforts help to strengthen critical systems by ensuring that services are delivered according to accepted standards of care and lead to desired outcomes.

Because QI is data-driven, performance must be measured in order for quality to be improved.

Performance measurement is the standardized collection of data that informs care teams how care is being provided and received and systems are functioning. These data are used to inform planning and improve care through the QI process. In the absence of good performance measurement, these planning and improvement efforts are otherwise often based primarily on people’s ideas and may not necessarily reflect what is happening. Standardized and uniformly applied indicators form the bedrock of performance measurement. These indicators let stakeholders know what is really happening in the clinic and whether changes that are made result in an actual improvement. Performance data are then used to identify opportunities to improve quality.

RELATIONSHIP BETWEEN RESEARCH, QUALITY MANAGEMENT, AND MONITORING AND EVALUATION

Quality measurement and improvement overlap with a number of other important activities that help ensure access to and delivery of effective care (see Table 1). All these activities are part of an evaluation process, helping to determine whether care is being delivered appropriately and whether desired outcomes are being achieved. However, there are important differences among these activities. Monitoring and evaluation (M&E) activities do not focus on how to address the gaps that are identified during the evaluation process. In addition, given the time frame of most formal evaluation, the results may reflect a system of care that has changed since the evaluation data were collected. Evaluation also may focus on longer-term goals that can only be measured after a number of years of program operation. However, the work done during the planning of an evaluation can feed
into QI efforts by identifying the steps of a program that are thought to be critical to achieve its stated goals. This information would then feed into decisions regarding where to focus performance measurement during program service delivery so that gaps that may serve as a barrier to achieving long-term program goals can be rapidly identified.

There is also an opportunity to learn from completed evaluations of similar programs, which may highlight areas having the greatest impact on the program’s success or failure. These are the areas that should be considered as targets for measurement. One way of determining areas of focus in evaluation is through the use of an evaluation logic model, a diagram that helps foster an overall understanding of how program inputs and processes are linked to outcomes and impact (see Figure 1, next page). For example, a logic model for a prevention of mother-to-child transmission of HIV (PMTCT) program, in which the planned impact is the improvement of HIV-free survival of children, would include an assessment of resources (inputs) invested in the program, program activities (e.g., HIV testing, dispensing of

| Table 1. Comparison of Quality Improvement, Monitoring or Accountability, and Clinical Research |
|---------------------------------|---------------------------------|---------------------------------|
| Aspect                          | Quality Improvement             | Monitoring or Accountability    | Clinical Research               |
| Aim                             | Improvement of care             | Assessment of program function; comparison, choice, reassurance, spurring of change | New knowledge                  |
| Test observability              | Test observable                 | No test, evaluates current performance | Test can be blinded             |
| Bias                            | Accept consistent bias          | Measure and adjust to reduce bias | Design to eliminate bias (e.g., randomization, case mix) |
| Sample size                     | “Just enough” data, small sequential samples | Obtain 100% of available relevant data | More data ensures adequate power, single sample size |
| Availability of data            | Collected for immediate feedback and further work | Collected for reporting, used when all data available | Data available only at end of study |
| Flexibility of hypothesis       | Hypothesis flexible, changes as learning takes place | No hypothesis | Fixed hypothesis |
| Testing strategy                | Sequential tests                | No tests                        | One large test, statistical significance critical |
| Confidentiality of data         | Data used only by those involved in the improvement project | Program/site data often available for public consumption | Research subjects’ identities protected, results of study published |

current performance leading to changes in processes while the program is ongoing, with the goal of rapidly improving overall quality of care.

IMPLEMENTING QUALITY-MANAGEMENT PROGRAMS FOR HIV CARE IN RESOURCE-LIMITED SETTINGS

The effectiveness of HIV care and treatment is directly linked to the quality of care provided. In the United States, measuring quality in HIV care has led to a better understanding of the patient, provider, and site factors associated with quality of care.12-14 There is also a growing effort to examine and improve the quality of HIV services in resource-limited settings. Groups such as HIVQUAL International, the Quality Assurance Project (QAP), the Institute for Healthcare Improvement (IHI), the Regional Center for
Guidelines are (ideally) evidence-based clinical recommendations that may ultimately become the standard of care. They are used to communicate overall approaches for a particular health-care activity in order to achieve the desired results. Ideally, these are national (Ministry of Health) or international (e.g., World Health Organization, Joint United Nations Program on HIV/AIDS) guidelines that have been developed based on scientific evidence and are appropriate to the program setting and available resources. Examples include guidelines for ART care, TB diagnosis and treatment, and PMTCT.

Standards of care are explicit statements of expected performance for a given health-care activity. They can be developed from guidelines but can also be developed through a community- or evidence-informed process. The latter approach can be taken when there are no available guidelines from which the standards can be derived. In this instance, a group of relevant stakeholders (experts, consumers, providers) can develop standards that reflect the available evidence and local constraints. An example of a standard of care based on WHO guidelines would be “All patients living with HIV who are WHO clinical stage IV should be started on ART.” An example of an evidence- or community-informed standard would be “All patients receiving ART should receive nutritional support if malnutrition or food insecurity is identified.”

Performance Measurement
The first step to improving quality is understanding how care is currently being provided. In deciding what to measure, it is helpful to think about quality in three categories: structure, process, and outcomes. At a clinic level, structure, process and selected outcomes are the easiest to measure, while longer-term or less common outcomes are more often the focus of longer-term evaluation and oversight (such as at the district or national level). Structure focuses on the quality of the inputs into the program (e.g., resources, staff, physical infrastructure), while process is concerned with how the planned activities are implemented (e.g., number served, percent on appropriate medication, adherence to care). Outcomes measurement focuses on the effect of the services (e.g., improved CD4 counts for patients on ART, decreased loss to follow-up) and may also offer potential targets for QI at the clinic level. To measure quality, there must also be agreement about how care should be delivered. These quality standards are broadly defined by national guidelines, and more specifically through standards of care.

Next Steps in Measuring Quality
Measuring quality requires three critical steps: (1) determining what will be measured, (2) collecting performance data, and (3) analyzing the data to identify potential areas for improvement or replication. Performance measurement can focus on quantitative data (how many, how often) or qualitative data (how it is being done, how the programmatic/system is functioning, patient satisfaction).
Routinely Measuring and Improving the Quality of HIV Care for Adults and Children: Lessons from Project HEART

The Elizabeth Glaser Pediatric AIDS Foundation (EGPAF) Project HEART, funded by the U.S. President’s Emergency Plan for AIDS Relief (PEPFAR), has been working with in-country partners (South Africa, Côte d’Ivoire, Zambia, Mozambique, and Tanzania) and John Snow Inc. to develop and implement an approach to routinely measure and improve the quality of HIV care for adults and children. This experience has highlighted the need to initially focus on measuring important areas of care, such as opportunistic infection (OI) screening and prophylaxis, HIV diagnosis in children, and management of antiretroviral therapy (ART). As the work progressed, the need to assist sites in understanding quality management was also identified, and so efforts are transitioning to focus on building internal capacity at the Project HEART country-office level initially, and ultimately at each site. Critical components of this approach have included close engagement with sites and feedback of performance measurement results, flexibility to adapt what is measured over time, and initial use of external quality experts to jump-start the efforts through performance measurement and support for improvement. Over time, these experts are transitioning into a capacity-building role by providing training and preceptorships.

The current work, which builds on the HIVQUAL approach as well as other models of measurement and improvement, focuses on building a programmatic structure and systems to support performance measurement and QI activities at the site and program level. The goal of these efforts initially is to support sites in QI efforts while building capacity so that the sites can ultimately take ownership of these efforts. Experts provide the initial on-the-ground performance measurement and QI, while at the same time infrastructure is built up through training and support to facilitate the transition to a program and site-led effort. This approach has been successfully used by a number of groups and represents a sustainable approach to measuring and improving quality during the rapid scale-up of ART. This approach also allows sites to mature at different rates until they are able to provide internal leadership and capacity for quality-management activities.

The development of indicators to identify the specific performance areas and the specific measures that define how and what will be measured is the next step in measuring quality. A quality-of-care indicator can be defined as “an aspect of patient care that is measured to evaluate the extent to which a facility provides or achieves a particular element of care.” A measure is then developed to gauge explicitly how well a clinic is providing the chosen element of care or achieving the desired outcome. The measure should ideally specify the population eligible for the element of care, what care should be delivered, and how it will be measured. The following example shows the progression in development from a guideline to an indicator, and then from an indicator to a measure:
• **Guideline:** Cotrimoxazole should be used in patients at WHO clinical stage IV or with a CD4 count less than 200 cells/mm$^3$.

• **Indicator:** Cotrimoxazole use among patients at WHO clinical stage IV or CD4 count less than 200 cells/mm$^3$.

• **Measure:** Proportion of patients at WHO clinical stage IV or CD4 count less than 200 cells/mm$^3$ who are currently being prescribed cotrimoxazole. (An alternative measure would be proportion of patients at WHO clinical stage IV or CD4 count less than 200 cells/mm$^3$ for whom cotrimoxazole is being dispensed.)

**Choosing What to Measure**

It is tempting to try to measure all aspects of care when initiating performance measurement. However, this is an overwhelming task and can result in a system that focuses only on measurement rather than on improvement. Therefore, it is important to identify specific areas for measurement and, within these areas, a limited number of indicators to measure. These decisions should be based on discussions with relevant stakeholders and should incorporate existing knowledge about how the program is currently functioning (i.e., areas of concern may be chosen as a priority). Other elements that should be considered include feasibility of measuring, relevance to the program, and whether the program can improve the area being measured. For example, although staffing may be viewed as a major issue for quality and be measurable, an individual site may not be able to change patterns of staffing directly, and so improvement by the site is not achievable. Another area, such as decreasing missed visits, would be an example where performance can be measured (number of missed visits), relevance is high, and improvements can be made (e.g., outreach efforts, linking with nongovernmental organizations, improving systems to identify missed visits).

**Coordinating Work to Measure and Improve Quality with Other Activities and Key Partners**

When developing an approach to measure quality, efforts should be coordinated with other ongoing monitoring and reporting activities that reflect the needs and requirements of national and local governmental agencies as well as other key partners. Many programs, such as TB control and treatment and maternal and child health, may have existing requirements that include substantial data recording and collection. Coordinating efforts with other programs will also help develop a standardized framework for measuring and documentation that will ultimately maximize efficiency, help to avoid duplication, and improve effectiveness by facilitating the sharing of data for improvement and planning. Integration of these data collection efforts with quality measurement will maximize the use of existing resources and increase integration and coordination between HIV and other related programs.

**Optimal Approach to Data Collection**

The development of a data collection plan will help organize the process of selecting and defining areas to be measured. This plan should include the available data, how they will be collected, how they will be analyzed, and who will analyze them. In making these decisions, the program teams should be aware of the time requirements and degree of difficulty associated with the collection of each measure, as well as the number of patients to be sampled and the data elements needed.

Data sources may include clinic forms, existing databases, and M&E data. Other valuable sources include existing clinical logs or registers, and any other data collection or evaluation that is being done at the site. Data collection should be undertaken using standardized tools and clearly defined criteria to ensure uniform collection. Borrowing
existing tools that have been successfully used and, if possible, validated in similar settings will save time and help ensure relevancy. However, simple is usually best; the skills of data capturers and site resources will often determine which procedures are used.

Data used for measurement of quality and changes in performance need to be as accurate as possible, but not so cumbersome to collect that repeated measurement is not feasible. To ensure the reliability of data, program teams should make certain that indicators are clearly defined, that measurement is standardized, and that staff involved in data collection and entry have adequate training. Ideally, data collection should be a routine activity integrated into daily tasks. For example, needed data elements can be captured in clinical records, which can then be periodically extracted as needed for performance measurement. In settings where electronic databases have been introduced, quality measures should be integrated into these information systems and queries established to produce the desired performance data. Data should be collected regularly over time, so trends in the indicators can be monitored. As various approaches to data collection are developed, it is also important to keep the goals of this activity in mind—namely, to identify the presence and causes of systemic problems that can result in poorer quality, and to guide management decisions.

Ensuring Feedback of the Data and Results
One important component of measuring quality is ensuring that data are fed back to the providers (and to the sites if data are collected by an entity responsible for oversight of multiple sites). This work will increase buy-in and the value of the data to those responsible for collection and providing services. Data should be displayed in a manner that is tailored to meet the needs and comfort level of the intended audience. Staff may have varied experience with data interpretation and may benefit from simple graphs and charts. These visual presentations allow them to easily see where change is needed and what changes have been observed, and will increase their engagement in efforts to measure and improve quality.

Quality Improvement
Quality work does not stop with measurement and feedback. Once areas for improvement are identified, appropriate interventions must be developed and implemented. To know whether quality has been improved, performance must be measured and remeasured as changes are made to address the gaps in performance. Important steps to improving quality will include the following:

- Identifying where to start (identifying problems and choosing which to address)
- Choosing the most appropriate approaches to improving quality
- Evaluating the impact of improvements
- Assessing sustainability and the extension of improvements (sharing lessons learned)

QI work is best done by a team that can focus on the areas where improvement is needed, develop potential solutions, and test them to see if change occurs. The team ideally includes individuals who are involved in the area of focus (e.g., providers, other staff) as well as other individuals who bring in relevant skills or knowledge, such as quality-management staff from district or central levels, consumers, and others.

There are a number of approaches to determine where the potential gaps in care inputs or processes may be occurring. One approach used to develop an in-depth understanding of the steps needed to achieve a desired standard of care at the clinic level is the flowchart (Figure 2). The flowchart outlines the processes that occur within a specific clinic to create a detailed sequence of events leading up to
the provision or receipt of an identified aspect of care. Engaging the care team as much as possible in developing the flowchart helps staff visualize a process so that it is easier to understand and improve, while simultaneously identifying potential sources of problems and solutions. Examples of processes conducive to this approach include CD4 testing, adherence counseling, and the tracking of patients who are lost to follow-up.

A slightly more complex approach to identifying potential causes of quality gaps and areas for improvement is the fishbone diagram (Figure 3). Fishbone, or cause-and-effect, diagrams are used to map variables that may influence whether or not a process or outcome is achieved. The fishbone skeleton is used to identify the key categories (e.g., staff, procedures, resources, and environment) contributing to a given process. The team then identifies gaps in the process and assigns causes of and solutions for these gaps to each category. From there, the team members identify areas they think will most likely improve the care process. These areas then become the target of improvement activities.

Once a specific component of the system has been targeted for improvement, the team will develop an intervention to address the area of concern. This work should be performed as rapidly as possible and tested on a small scale to determine whether it is feasible and effective (rapid cycles of change). One widely utilized method for testing QI interventions is called the Plan-Do-Study-Act (PDSA) cycle. In this method, the team plans the improvement (Plan); implements it on a small
scale (Do); evaluates it to see if the desired change occurred (Study); and then acts to modify, expand, or choose a different step in the system depending on the results (Act). The process is then repeated until an effective change has been identified and integrated into the care system. Other variations on this approach have also been used in working to improve quality in clinical care. For all these activities, training in how to use them and support for their application is important so that the approaches implemented are effective and relevant.

**EVALUATING THE QUALITY-MANAGEMENT PROGRAM**

An important activity that is sometimes overlooked is the assessment of how well the quality-management program is working. The program team should periodically assess whether the planned activities for measuring quality are being carried out and whether the expected improvements in quality are being seen. This assessment is important to ensure that the efforts and resources put into the program are achieving the desired outcomes. The process should be treated as an opportunity for self-assessment rather than a required formal evaluation. Questions asked should include: “Is performance being measured?” “Are the results being used to improve care?” and “Is quality being improved?” This self-assessment helps the members of the program team learn and respond to past performance in order to strengthen their work and sustain QI efforts.

**Engaging Consumers in Quality Management**

Ultimately it is the patients who will decide whether the services they receive are responsive to their needs and whether they are able and willing to follow through with care that is needed to achieve the desired outcomes. For example, as patients begin to feel better following initiation of ART, their motivation to keep appointments or take medication may wane, thus compromising the likelihood of achieving the promised benefits of care and treatment. Although it is a patient’s right to make decisions about his or her health, the interaction between patient and provider may often influence the likelihood that a patient adheres to the recommended care and treatment. These choices are influenced
by the consumer’s perception of whether or not his or her concerns and needs are being addressed and goals (e.g., improved quality of life, longer life) are being met. These perceptions on the part of the consumer are sometimes described as the experiential dimension of health care. While the technical dimension of health care is the traditional focus of quality measurement, the experiential dimension plays an equally important role in determining whether quality care is received.28

Consumers may identify needs or concerns that are not recognized or prioritized by providers. Soliciting consumer input about the system of care is important and can be achieved through several different methods.1,29 The simplest method involves the use of exit interviews that ask patients whether their needs have been addressed, what is their level of satisfaction with the care received, and whether they can explain what they were advised on during the visit. Other methods include group interviews and written surveys, depending on the literacy level of the population. The information obtained from these interviews or surveys can be included in the quality-management program to improve health-worker and/or system performance. As the relationship between the care providers and patient community grows over time, patients may become an integral part of the quality program and participate in processes designed to monitor and improve care.

CONCLUSION

While the demands of rapidly expanding HIV care programs can be overwhelming, focusing on quality is an important and achievable step in providing effective care. The approaches described in this chapter can easily be adapted for a range of clinical settings to engage staff in quality-management activities. Improving quality of care in the context of HIV care in resource-limited settings is achievable and will result in benefits to patients, staff, and programs in the short term and for the future.

Achieving and Maintaining Quality in HIV Care: Lessons Learned from Zambia

Mary Morris and Nicole M. Quiterio

W ith an increasing number of patients seeking services and treatment for HIV, the need to achieve and maintain quality of care presents major challenges to HIV providers. Between 2004 and 2007, the Zambian Ministry of Health (MOH) initiated a rapid scale-up of delivery of antiretroviral therapy (ART) to HIV-positive people who were eligible for treatment based on World Health Organization (WHO) clinical staging and CD4 cell counts. During this time 105,000 patients were enrolled in HIV care, and 54,000 people were commenced on ART. An external audit performed 15 months after the program began showed inadequate health-worker practices (e.g., failing to start eligible patients on *Pneumocystis carinii* (jiroveci) pneumonia [PCP] prophylaxis, and not ordering the appropriate laboratory investigations according to national guidelines). These errors needed to be corrected and health-worker performance improved in order to achieve improved quality of care in the face of rapid scale-up.

Quality of care is dependent upon multiple factors, including health-worker performance; the attributes of the work environment; client behavior and/or receptiveness; and the provision of structure, space, and the necessary tools, equipment, and supplies to enable health workers to do their jobs. To improve health-worker performance, the Centre for Infectious Disease Research in Zambia (CIDRZ) devised a quality assurance program based on these factors, which utilized multidimensional interventions including infrastructure development, training, mentoring, and continuous quality improvement. This chapter reports our experiences implementing this program in Lusaka, Zambia, and serves as a model for low- and middle-income countries seeking to provide patients with a high quality of care despite human resource shortages and increasing numbers of patients seeking care.

**BACKGROUND**

Project HEART is an HIV care and treatment program funded by the U.S. President’s Emergency Plan for AIDS Relief (PEPFAR) and managed by the Elizabeth Glaser Pediatric AIDS Foundation (EGPAF). Since 2001, EGPAF has been working with its partner organization, CIDRZ, which has...
established 45 HIV care and treatment sites in four provinces. CIDRZ, with support from EGPAF, provides comprehensive, decentralized HIV treatment services in Zambia through engagement in the following activities: providing ART, improving and renovating infrastructure, providing essential laboratory equipment for diagnosis and monitoring, establishing referral and follow-up systems, training health-care providers, and strengthening health management information systems (HMIS) and supply logistics.

Zambia faces enormous challenges to enroll and maintain the 330,000 people who require treatment for HIV in longitudinal care. The greatest challenges to providing quality care for such large numbers include a shortage of human resources, infrastructure and supply deficits, and inexperience with chronic care. According to the MOH, Zambia has 646 of the recommended 2,300 doctors, and 6,096 of the recommended 16,732 nurses—a deficit of 1,654 and 10,636, respectively. The General Nursing Council recommends a nurse-to-patient ratio of 1:6; however, in many hospitals and clinics, the current nurse-to-patient ratio is 1:100, which results in increased workloads and compromised quality of care. The demand for an increased number of trained professionals is unmet due to a lack of training institutes and lengthy training programs with few graduates. The current rate of graduation from nursing schools is between 400 and 600 nurses per year. At this rate, assuming no attrition, it is estimated that recommended clinician-to-patient ratios and nurse-to-patient ratios will not be reached until 2045. Attrition is defined as health-care workers leaving government service for various reasons, such as to work in the private sector or in other countries, to change careers, or due to death from HIV itself; from 2003 to 2004, mortality accounted for 38% of staff attrition in Zambia.

THEORETICAL FRAMEWORK FOR PERFORMANCE IMPROVEMENT

In the late 1960s, Avedis Donabedian, a renowned professor of public health, first introduced the concept of assessing quality of care through evaluating structure, process, and patient outcomes. Over the next few decades, this approach became a dominant and accepted paradigm for the evaluation of quality of care. Donabedian asserted that structure, as in the facilities and staffing of a site, should be adequate in order to provide a high quality of care. Process assumes that if proper procedures are followed, improvements in health care will result. Outcomes assume that patients’ current and future health is attributed to the health care provided, and that staff benefit as a consequence of providing that care. His model provides a useful theoretical framework for the accreditation of health facilities and the development of performance appraisal methods. Yet it does not fully address the particular challenges faced by health-care workers in resource-limited settings, who may not benefit as a consequence of providing care and who may not be motivated to improve their performance. Good health-worker performance is essential for effective delivery of health services. Poor health-worker performance contributes to reduced use of health facilities and harmful health practices. If health-care performance is inadequate, adherence to guidelines is poor and interventions are not implemented to prevent sickness and death.

A number of cognitive and behavioral theories are used as a basis for understanding and changing health-worker practices. For instance, cognitive theory assumes that undesirable behavior is caused by lack of information. Therefore, we disseminate information on evidence-based guidelines through formal trainings and by circulating written guidelines. However, we also recognize that training and the dissemination of written guidelines alone will not change behavior. By disseminating written
guidelines and standard operating procedures, and conducting trainings and clinical update meetings, we clearly communicate our expectations to health-care workers.

Improving health-worker performance requires adapting to an individual’s stage of change. Depending on their environment, personal experiences, and readiness to change, people progress through five distinct stages of change: precontemplation, contemplation, preparation, action, and maintenance.7 An individual may cycle through these stages several times before maintaining change.7 The behavioral change model advocates tailoring interventions to the recipient’s specific stage of readiness.7 In our setting, expectations and intervention designs differ based on how long sites have been operating; training and support are tailored to the level of staff experience and competence at a given site. Assuming that external stimuli can influence behavior, we use interventions such as placing reminders in patient files for health workers to see (e.g., “repeat CD4 cell count to assess treatment failure”). We model desired performance while providing clinical mentoring, and regularly measure performance and provide feedback on performance to each site.2 Good performance is recognized by the provision of incentives and rewards.

Diffusion-of-innovation theory explains how social groups influence change among peers. This theory asserts that most individuals are initially reluctant to adopt new ideas. Their acceptance of change requires that they pass through several phases, including awareness, interest, evaluation, and trial.7 Health-care workers’ responses to innovation can be grouped according to the speed at which the individuals adopt innovation. Some individuals are innovators, while others are ambivalent or resist innovation, particularly if they do not see any personal benefit from doing so, have a general lack of motivation, or are burned out.7 In our twinning program, we use experienced leaders of successful sites (the “innovators”) to influence staff at poorly performing health facilities to change their practices and improve their standards of care.

QUALITY ASSURANCE TOOLS

Our quality assurance program employs a systematic approach to optimize health-worker performance through training, mentoring, and continuous quality improvement. Before implementing new sites, an assessment of structure and space is conducted so that all renovations are completed before services are commenced. Site-specific preparation first involves providing all the necessary medical equipment and supplies, and training medical staff. Information on drug toxicities, treatment failure, national guidelines, and treatment algorithms are disseminated to all clinics. Data forms guide health workers through history taking, review of symptoms, physical examinations, WHO staging, assessment, care planning, ordering of investigations, and follow-up. Detailed standard operating procedures and care algorithms guide clinicians through the management of complex conditions and drug toxicities. Thereafter, continuous training and mentoring are provided to all sites, with a designated nurse spending two days per week at the site providing ongoing mentoring and supportive supervision.

PERFORMANCE MEASUREMENT AND FEEDBACK

The objective of the quality improvement program is to measure whether sites are providing adequate and appropriate care and treatment services in accordance with national guidelines.4 To assess quality of care, indicators are selected that are relevant, measurable, and routinely available in the patient files or database. Initially developed for CIDRZ-supported sites, an electronic patient tracking
From the ground up: Laying a strong foundation

Some of the indicators that are routinely measured include the following:

- Percentage of patients who have received a baseline CD4 count
- Percentage of patients who have received a repeat CD4 count
- Percentage of patients who have received baseline liver and kidney function tests
- Percentage of patients on zidovudine who have had their hemoglobin measured
- Percentage of patients who have appropriately started PCP prophylaxis

Quality assurance reports (Table 1) provide information on the performance of each clinic, making it possible to monitor trends in performance based on certain quality indicators. Feedback is then provided to the clinics based on this information. Meetings are held to discuss each clinic’s strengths and weaknesses and to formulate interventions to improve performance. Since performance is measured every three months, sites can evaluate their performance—in individual areas and overall—compared with other clinics over time.

Table 1. Sample Quarterly Performance Report

The system (SmartCare) has now been adopted as the national patient tracking system for HIV care and treatment programs throughout Zambia. Relevant demographic, laboratory, and clinical information on all patients enrolled in care and treatment programs, including those on ART, is entered into the system. The system is used to track patients, assess patient outcomes, and provide stakeholders with program information.
After 37 months of program implementation, in June 2007, Project HEART Zambia was operational at 39 sites in four provinces (Lusaka, Southern, Eastern, and Western provinces). More than 105,000 patients had been enrolled and 54,000 patients were on ART. Quarterly performance reports generated for the same 14 clinics in Lusaka during this period showed improvements in the majority of indicators: 85% of patients had received a baseline CD4 count, 88% of patients had received a repeat CD4 count, 89% of patients had a baseline hemoglobin measurement on file, 85% of patients had received baseline liver and kidney function tests, 67% of patients were appropriately on PCP prophylaxis, and 83% of patients had been seen by a clinician in the last three months (see Figure 1, next page).

Training and Clinical MentorIng

Medical officers, nurses, and clinical officers attend basic trainings in adult and pediatric HIV care and treatment in addition to receiving training on behavior change and counseling. Thereafter, training is provided on an as-needed basis, with clinical updates provided annually to selected staff.

Clinical mentoring is conducted at various levels within the program. The role of the clinical mentor is to provide on-site, continuous, supportive mentoring to inexperienced clinicians and nurses to improve the quality of patient care. Experienced HIV clinicians from the United States and Canada provide clinical updates and train Zambian doctors, clinical officers, and experienced nurses to become clinical mentors. Clinical mentors are trained in the latest guidelines for ART and clinical mentorship. Mentors also attend weekly clinical update meetings, participate in online medical education sessions, and attend periodic national meetings to stay current on the evolving practice of...
Recently, each clinic has established a quality committee comprised of clinic staff and community members who actively address quality issues and concerns. At some district clinics, the quality committee has placed suggestion boxes in the waiting area to obtain anonymous feedback from clients on ways to improve services. Patient suggestions to improve care are discussed at monthly quality committee meetings, and changes are implemented when possible. Every morning, group education sessions led by peer educators (community members who are HIV-positive and trained in HIV counseling) address adherence issues at each clinic; topics covered range from how to manage missed clinic visits or skipped doses to family issues relating to HIV. All patients are encouraged to attend.

**BUILDING SUSTAINABLE SYSTEMS**

Currently, each clinic has established a quality committee comprised of clinic staff and community members who actively address quality issues and concerns. At some district clinics, the quality committee has placed suggestion boxes in the waiting area to obtain anonymous feedback from clients on ways to improve services. Patient suggestions to improve care are discussed at monthly quality committee meetings, and changes are implemented when possible. Every morning, group education sessions led by peer educators (community members who are HIV-positive and trained in HIV counseling) address adherence issues at each clinic; topics covered range from how to manage missed clinic visits or skipped doses to family issues relating to HIV. All patients are encouraged to attend.

**Figure 1. Clinical care performance for 14 Lusaka district clinics in operation before June 2005**

Note: Graphs represent the percentage of patients on ART who met each specific quality-of-clinical-care indicator. ALT = alanine aminotransferase, HB = hemoglobin
Exchange visits are conducted for nurses and clinicians between city and provincial sites to encourage positive peer social influence and build sustainability, ownership, and interest in continuous quality improvement. The sites that are performing well provide supportive supervision and mentoring to less experienced sites. Since the implementation of exchange visits, the quality of care in provincial and Lusaka sites has improved significantly. The provincial and district health offices are also responsible for assessing quality of care. Meetings are held at the designated clinics to review quality performance reports, which later are presented to the MOH. By providing feedback to clinics, the provincial and district health offices enhance collaboration, communication, and ownership of the quality improvement program.

**STRATEGIES TO IMPROVE HEALTH-WORKER PERFORMANCE: CHALLENGES AND INTERVENTIONS**

**Failure to Order Appropriate Laboratory Investigations and Assess Patients on Severity of Problems**

At program initiation, many clinicians were not ordering the appropriate laboratory investigations (e.g., baseline hemoglobin for patients starting zidovudine, baseline liver function tests, or repeat CD4 cell counts per national guidelines) or were failing to switch antiretroviral (ARV) drugs due to toxicities or treatment failure. During our inquiries with the clinic staff, it became evident that nurses were not authorized to request or interpret laboratory investigations, failed to prioritize patients according to the severity of their problems, and lacked knowledge about drug toxicities and treatment failure. Once these shortcomings were identified, a triage training to address these factors was developed, which focuses on patient assessment and the management of urgent problems, the recognition of toxicities and severe illness, and the interpretation of laboratory investigations. This training has enabled nurses to triage patients appropriately and to ensure that patients receive appropriate laboratory investigations and are reviewed in a timely manner by physicians.

After triage training, nurses undergo advanced training on care of stable HIV patients based on the WHO Integrated Management of Adult and Adolescent Illness (IMAI). This five-day training focuses on several components of clinical evaluation, including HIV disease staging, opportunistic infection prophylaxis and treatment, ART eligibility, and ARV drug toxicity and management. A key focus of the training is early recognition of signs and symptoms requiring referral to a tertiary-level facility.

**Staff Shortages, Retention, and Motivation**

Recent statistics indicate that Zambia has an estimated seven doctors and 113 nurses per 100,000 people, which is less than one-third of the target number for doctors and less than one-half of the required nurses. To address these shortages, and to motivate and retain health-care workers, we provide salary support, training, and continuing education opportunities. In addition, health workers are provided with access to free, confidential health care, either on-site or at a designated clinic. Nevertheless, staff shortages, retention, and lack of motivation remain the greatest challenges to achieving and maintaining good quality of care. While the number of health-care workers remains deficient, the number of patients being enrolled and commencing ART continues to grow. To respond to the ever-increasing patient demand, we utilize task shifting, a process of delegating tasks from more specialized to less specialized health workers. This approach, which has been proposed by WHO and others as a possible short-term solution...
to the dire human resource shortages in the health-care sector, has been effective in similar settings in Africa. However, the ability to expand the role of lay and professional health-care workers is limited. As individuals take on more responsibilities, they need to receive appropriate recognition and incentives. While we offer overtime salary support, we realize that this is a short-term solution that does not address chronic staffing deficiencies.

**Deficiencies in Provincial Laboratory Capacity**

Despite multiple trainings in laboratory capacity building, the ability to maintain a consistent supply of reagents and ensure the proper functioning of laboratory equipment remains elusive. A combination of poor logistics and supply forecasting, coupled with lack of experience in maintaining equipment and staff de-motivation, have contributed to the laboratory capacity deficiencies. To address this problem, we are enlisting teams that work closely with provincial sites to build capacity for equipment maintenance. We are also considering novel ideas for performance-based financing, in which staff are paid for each test completed.

**Limited Site Capacity**

A number of sites are already operating at maximum capacity, which creates a significant strain on staff working in a limited space. Filing systems have become disorganized, consulting rooms are crowded, waiting lines are long, and staff are tired. To address these challenges, we have constructed temporary walls and filing shelves to increase the number of consulting rooms and provide additional filing space. In some clinics, we have instituted a system of preparing files the previous day for the next day’s appointments. We have lengthened the time between follow-up appointments for stable patients who are now managed by nurses. We are exploring the possibility of instituting mobile clinics, where trained clinicians and other staff from district health clinics regularly visit health posts to provide clinical care and mentoring to health post staff. This will enable staff at health posts to manage stable patients, thereby off-loading significant numbers of patients from clinics that have exceeded their capacity. This approach has been tried in a number of settings, with reported success.

**KEY POINTS SUMMARY**

- The quality of health care depends on multiple factors, including patient and health-worker behavior, as well as workplace and environmental factors.
- In order to improve the quality of care, we have implemented a number of multifaceted interventions that addressed a variety of shortcomings.
- Quality of care is monitored at regular intervals, deficiencies are identified, feedback is provided to each site, and appropriate interventions are developed to improve performance; then the cycle is repeated.
- Continuous training, mentoring, and communication are essential for high-quality performance.
- Written guidelines and job aids are needed to support both experienced and inexperienced health-care workers.
- Improving health-worker performance is dependent not only on education and clinical mentoring, but also on regular performance measurement and feedback; emphasis should be placed on understanding and addressing conditions that support staff motivation and retention.

HUMAN RIGHTS AND HIV CARE
Universal Access: Are National Strategic Plans Sensitive to Human Rights?
Daniel Tarantola and Sofia Gruskin

Twenty-Five Years and 23 Million deaths after the emergence of HIV/AIDS, the attributes of successful national responses are known and evidence supporting the proliferation of effective interventions is abundantly available. Yet no single analytical framework—whether grounded in economics, social sciences, ethics, or human rights—can determine, to everyone’s satisfaction, who should benefit from HIV-related services and in what order of priority. It is also impossible to stipulate what level of services should be provided to each affected population and which segments of the population should benefit more quickly from the best available care. The application of a human rights framework does, however, ensure that policies and programs are as effective as possible and that the related processes, as well as their planned outcomes, are to the greatest extent possible based on the principles of justice, dignity, and fairness.

Countries that failed in their early HIV/AIDS responses, including China, Russia, and South Africa, led efforts that were characterized by inequality, persisting discrimination, denial of access, and lack of participation of affected communities. These failures, in turn, perpetuated the state of disempowerment and risk of acquiring HIV infection among vulnerable communities and individuals. Conversely, countries that achieved great strides in their initial HIV/AIDS responses, including Australia, Brazil, the Netherlands, Switzerland, Thailand, and Uganda, did so by applying human rights principles, such as participation, nondiscrimination, and access to information, as well as by establishing policies and programs for the provision of essential services and lifesaving technologies.

Yet, in some of these countries, not all populations have benefited equally from the application of these principles. In Thailand, for example, injecting drug users continue to be regularly constrained in their ability to access essential HIV-related services.

The Role of Human Rights and Their Emergence in the HIV Discourse

Human rights, as used in this chapter, comprise the legally binding commitments of governments under international human rights law. Every country in the world is party to at least one human rights treaty, and all have made rights-related commitments in relation to HIV, such as those made during various recent United Nations (UN) General Assembly sessions (e.g., the 2000 Millennium
Respect for human rights is critical to preventing the spread of HIV and reducing AIDS-related stigma and discrimination. Human rights violations against people living with HIV are often in the form of
• restricted or limited access to medical care and health services;
• barriers to employment;
• mandatory HIV testing;
• restrictions on freedom of movement;
• issues raised by practices such as name reporting, partner notification, and confidentiality; and
• deportation of HIV-positive foreigners.

In order for human rights to be respected and enforced throughout the world, states must incorporate them into domestic legislation. States commit themselves to international human rights obligations when they ratify human rights conventions. They additionally recognize human rights principles when they endorse international declarations, such as the Declaration of Commitment on HIV/AIDS, which was endorsed by 189 countries in 2001.

Human Rights in the Context of HIV/AIDS: Government Responsibilities
In the field of international law, there are no binding legal instruments regarding HIV/AIDS. However, there is an established network of international treaties, as well as other recommendations, that have achieved the status of legally binding norms.

For every human right, governments have three responsibilities: states must respect, protect, and fulfill the right.

- **Respecting the right** means that states cannot violate the right directly.
- **Protecting the right** means that states must prevent violations of rights by nonstate actors and offer reparation if a right is violated.
- **Fulfilling the right** means that states must take all appropriate legislative, administrative, and judicial measures in order to realize the right.

At the United Nations General Assembly Special Session on HIV/AIDS, states committed themselves to “by 2003 enact, strengthen or enforce, as appropriate, legislation, regulations and other measures to eliminate all forms of discrimination against and to ensure the full enjoyment of all human rights and fundamental freedoms by people living with HIV/AIDS.”

Governments are therefore accountable for their actions toward people living with HIV because of their responsibility to uphold human rights.

**Important International Human Rights Instruments and Other Declarations**
- United Nations Charter, 1945
- Universal Declaration of Human Rights, 1948
- International Covenant on Civil and Political Rights, 1976
- International Covenant on Economic, Social and Cultural Rights, 1976
Development Goals, the 2001 Declaration of Commitment on HIV/AIDS, and the 2006 Political Declaration on Universal Access).10-12

The first global strategy on HIV/AIDS, launched by the World Health Organization (WHO) in 1987, aimed to reduce the transmission of HIV, minimize its impact on individuals and communities, and foster international cooperation and solidarity. The strategy was primarily focused on risk reduction through access to information, education, and services, as well as through the creation of a supportive environment. Attention to human rights was largely grounded in the recognition that the HIV-related human rights violations occurring around the world were undermining the public-health impact of prevention initiatives. Examples of such abuses by governments or by people acting on their behalf included neglect or tolerance of violence within families and communities, mandatory testing and detainment of vulnerable populations, and denial of inheritance and property rights, as well as denial of access to food, housing, marriage, education, medical care, international travel, health insurance, and employment.3,13-16

Largely due to strong advocacy from members of civil society, as well as WHO and the Joint United Nations Program on HIV/AIDS (UNAIDS), human rights gradually began to be included in the public discourse on HIV/AIDS; this led to human rights principles being incorporated into international as well as most national HIV/AIDS policies and plans.17 It is troubling to imagine what the HIV response would look like without attention to human rights, especially considering the tendency of governments to enact restrictive laws while condoning or turning a blind eye to human rights abuses.18 But as national responses to HIV were being formulated and put into action in the late 1980s, it was not clear how significant a commitment to human rights would actually be in terms of the practical implementation of HIV policies and programs. Even today, in countries where the government understands and acknowledges the science of HIV infection, discrimination against vulnerable populations, including men who have sex with men, sex workers, and injecting drug users, continues to be the norm. This discrimination, both explicit and in its more masked forms, has consequently deprived many vulnerable groups of lifesaving access to prevention, care, treatment, and other forms of support. Additionally, the heightened vulnerability of women to HIV, even when formally recognized, is often not addressed through targeted, effective responses. For instance, even though more women than men live with HIV worldwide, it took decades of activism before there

- Denver Principles, 1983
- Ottawa Charter for Health Promotion, 1986
- Convention on the Rights of the Child, 1989
- World Conference on Human Rights, 1993
- Paris Declaration, 1994
- International Conference on Population and Development and the Cairo Plan of Action, 1994
- Millennium Declaration, 2000
- Abuja Declaration, 2001
- Declaration of Commitment on HIV/AIDS, 2001
- International Convention on the Protection of the Rights of All Migrant Workers and Members of Their Families, 2003
was widespread support for research into effective methods that could be used by women to protect themselves from HIV infection.

We know now that anchoring HIV strategies in human rights principles requires more than making statements and signing declarations; responding to violations only after they have occurred also fails to constitute an effective response. The value of human rights to HIV efforts extends beyond their moral or legal significance. What human rights distinctively contribute is an array of principles, norms, standards, and instruments conducive to shaping policy and enhancing accountability. The application of a human rights framework can therefore help ensure that the broad spectrum of activities that constitute a national response, from the determination of priorities and strategies to the measuring of outcomes and effectiveness, are based on the promotion of justice, dignity, and fairness, and that a level of accountability is built into every step of the decision-making process.

The current global framework for confronting HIV is universal access—“the scaling up of HIV prevention, treatment, care and support with the aim of coming as close as possible to the goal of universal access to treatment by 2010 for all those who need it.” Universal access, in addition to being a laudable goal, represents a leap forward from the earlier WHO/UNAIDS “3 by 5” initiative in terms of its integration of prevention with treatment and care, as well as its focus on national-level targets.

Human rights concepts are touched upon in the core documents supporting universal access, with reference made to how the application of these concepts can help ensure acceptable and equitable implementation, generate trust between providers and clients, encourage ongoing engagement with health services, and stimulate accountability in relation to national benchmarks and targets.

The principles of universal access are also reflected in many of the national frameworks for HIV/AIDS policy and program design created by individual governments. In many countries, human rights have both shaped the expected outcomes of the national HIV/AIDS response and defined the processes by which these responses should be carried out and accounted for. Some have called this approach a rights-based approach to HIV, which is in essence a strategy that builds upon the principles of equality and equity, accountability, empowerment, participation, nondiscrimination, and attention to vulnerable groups. A rights-based approach supports the need to ensure universal access and is particularly important in settings where the vulnerability of certain populations to HIV infection and/or their lack of access to treatment arises from a lack of recognition of their human rights, as is often the case for women, minorities (racial, ethnic, and sexual), injecting drug users, and other marginalized individuals and communities.

A RIGHTS-BASED APPROACH TO HIV

The rights-based approach was initially conceptualized in the mid-1990s as a “human rights-based approach to development programming” by the UN Development Program, but the understanding of what a rights-based approach actually means in the context of HIV/AIDS efforts has varied across sectors, disciplines, and organizations. A rights-based approach to HIV calls for attention to processes as well as outcomes and requires integration of human rights norms and standards into policies and programs. This includes, for example, the participation of vulnerable and affected populations in decisions that concern them and the accountability of governments for their actions—and inactions—in preventing the spread of HIV and mitigating its impact on society. A rights-based approach to HIV requires states to set their own benchmarks and targets, to the maximum of their capacities and resources, as well as to fulfill their obligations of
accountability. By focusing attention on outcomes, a rights-based approach evaluates achievements against set program targets. When both processes and outcomes are examined through a rights-based lens, not only what has been achieved but also how these achievements have occurred is brought to light. For example, a rising uptake of HIV testing services could be due to an increase in high-quality voluntary counseling and testing (VCT) services or to the introduction of mandatory testing of certain population groups. Although the short-term outcome may appear the same, from a human rights perspective the processes used to achieve this outcome are entirely different. The approach using VCT is appropriate in both human rights and public-health terms, whereas the latter approach involving mandatory testing may, in the long term, be viewed as detrimental from both perspectives.

Anchoring strategies in human rights through the application of a rights-based approach strengthens programs by drawing attention to the legal and policy context in which they operate. A rights-based approach also allows for the incorporation of human rights principles, such as nondiscrimination, into the delivery of services and can secure the participation of affected communities in the design, implementation, monitoring, and evaluation of interventions. In addition, human rights approaches assist in holding governments and intergovernmental agencies, in particular those belonging to the UN system, publicly accountable for their actions and inactions in relation to HIV programming. Finally, assessing programs based on human rights standards, with a focus on the accessibility of essential prevention, care, and treatment services, calls attention to the availability, accessibility, acceptability, and quality of services and goods, as well as outcomes among different population groups (Box 1).

The various components of a rights-based approach and their underlying principles are drawn from the core content of the Right to the Highest Attainable Standard of Health enshrined in international human rights law. These rights place

</thead>
<tbody>
<tr>
<td><strong>Human Rights / Rights.</strong> Human rights are legally guaranteed under international human rights law. They protect against actions that interfere with fundamental freedoms and human dignity, and support the agency of individuals and populations.</td>
</tr>
<tr>
<td><strong>Stigma and Discrimination.</strong> HIV/AIDS-related stigma is the process of devaluing people because of their real or perceived HIV/AIDS status, or that of their family or community. HIV/AIDS-related discrimination refers to the legal, institutional, and procedural ways people are denied access to their rights because of their real or perceived HIV/AIDS status, or based on real or perceived membership within already stigmatized and vulnerable groups such as sex workers and injecting drug users.</td>
</tr>
<tr>
<td><strong>Participation.</strong> Under human rights law, everyone is entitled to active, free, and meaningful participation and inclusion in, contribution to, and enjoyment of civil, economic, social, cultural, and political development. Ensuring the inclusion and full participation of all key stakeholders and affected communities, with particular attention to the greater involvement of people living with HIV, at every stage of HIV policymaking and programming is recognized as essential to an effective response.</td>
</tr>
<tr>
<td><strong>Vulnerable/Marginalized Groups.</strong> Vulnerable and marginalized groups are broadly defined in the majority of human rights documents as comprising simply the most vulnerable or marginalized segments of the population. In HIV literature, increasingly, these groups are called most-at-risk populations. Variation exists, but in all cases these are understood to include injecting drug users, men who have sex with men, sex workers, and increasingly prison inmates, migrants / mobile populations, and women and young people. Questions exist about this more inclusive definition, which seems to leave out only adult men.</td>
</tr>
</tbody>
</table>
Box 1. Definition of Terms (continued)

The 3AQ: The right to health has been defined by the Committee on Economic, Social and Cultural Rights to include the availability, accessibility, acceptability, and quality of the goods and services provided. This is commonly known as the 3AQ, and the components are defined as follows:

**Availability:** This requires making available, in sufficient quantity, functioning health-care facilities, goods, and services, as well as programs to address HIV and AIDS. Although these facilities, goods, and services will vary by context, they should address the underlying determinants of health, such as safe and potable drinking water and adequate sanitation facilities; hospitals, clinics, and other health-related buildings; trained medical and professional personnel receiving domestically competitive salaries; and essential medicines, as defined by WHO.

**Accessibility:** The concept of accessibility encompasses four distinct components:
1. **Nondiscrimination:** Health facilities, goods, and services must be available to all, especially the most vulnerable and affected populations.
2. **Physical accessibility:** Health facilities, goods, and services must be physically accessible to all sections of the population, especially vulnerable or marginalized groups.
3. **Affordability:** Health facilities, goods, and services must be affordable for all. Payments must be based on the principle of equity, ensuring accessibility of needed services, whether privately or publicly provided.
4. **Access to information:** Accessibility also includes the right to seek, receive, and impart information and ideas concerning health issues, but this does not impair the right to have personal health data, including the results of HIV tests, treated with confidentiality.

**Acceptability:** Acceptability requires that all health facilities, goods, and services be respectful of medical ethics and culturally appropriate, that is, respectful of the culture of individuals, minorities, peoples, and communities; sensitive to gender and life-cycle requirements; and designed to respect confidentiality and improve the health status of those concerned.

**Quality:** Goods and services must be scientifically and medically appropriate and of good quality. Good-quality services should include, inter alia, skilled medical personnel, scientifically approved and unexpired drugs and hospital equipment, safe and potable water, and adequate sanitation.

---

obligations on states regarding their own actions as well as those of nonstate actors within their jurisdiction (e.g., nongovernmental organizations, employers, the pharmaceutical industry, private health-care services, or insurance companies). The added value of a rights-based approach to HIV is to offer a method for analyzing, recognizing, and responding to the range of issues stemming from national HIV policies and programs at all stages of strategic development, operational planning, implementation, and monitoring (Figure 1).

As the resources available to support HIV/AIDS responses continue to increase, there is a widening gap between rhetorical statements that promote the integration of human rights in HIV/AIDS work and the actual operational and programmatic commitment to take action. The most troubling discrepancy may be between the commitments expressed by governments in such international forums as the World Health Assembly or the UN General Assembly and the actual practices that take place at the country level. A number of reasons can be posited for these discrepancies, including the reluctance of certain governments to acknowledge the existence and needs of communities whose behaviors are not in line with cultural mores, religious beliefs, or the law. Additionally, state authorities and sources of external support may feel that the urgency of responding to the HIV/AIDS crisis offsets concerns about human rights. In some instances, it may simply be the result of the oversights that can occur due to a lack of resources or inadequate training, or between the conceptualization stage of a rights-based approach at the policy level and the actual application of these concepts to programming. Also, a common practice among some organizations is to use human rights language to justify their work or make it more politically attractive, even though in practice nothing is being done differently. Finally, as ever larger amounts of money are available to those in the HIV/AIDS field, donors are increasingly tying future funding to program output indicators with short time frames, leaving little opportunity for attention to be paid to

Figure 1. A rights-based approach to HIV care and treatment policies, programs, and practice: core components of a rights-based approach and their relevance to stages of national strategic development and implementation
the broader structural issues raised by the application of a rights-based approach. It should be noted that an important step toward alleviating some of the obstacles mentioned here is to further expand and disseminate evidence in support of the assertion that universal access initiatives with a focus on human rights are more effective than initiatives that lack such a focus.

This chapter will review the extent to which national-level commitments on HIV prevention, care, and treatment regard human rights norms and standards as a step toward achieving more effective action. Our review examines, in a sample of countries, the congruence between national HIV strategic plans; relevant human rights norms and standards to which states subscribe when becoming party to international human rights treaties; and the stated rights-related commitments entrenched in the 2000 Millennium Development Goals (MDGs), the 2001 Declaration of Commitment on HIV/AIDS, and the 2006 UN General Assembly Resolution on Universal Access. Our review was not, however, able to examine the further gaps between the intent stated in national strategic plans (NSPs) and their actual implementation. This further analysis is highly desirable and strongly encouraged by the authors. Additional information that may shed light on such an effort could be drawn from the progress reports submitted by governments and civil society to UNAIDS in anticipation of the June 2008 UN General Assembly Special Session, during which reports on progress toward achieving the 2001 Declaration of Commitment targets were discussed.

A HUMAN RIGHTS ASSESSMENT OF HIV NATIONAL STRATEGIC PLANS

A sample of 14 countries was retained for this analysis. Countries were chosen to ensure inclusion of (1) all regions of the world; (2) different HIV prevalence/incidence rates within both generalized and concentrated epidemics; (3) nations that host the majority of people living with HIV (resulting in a deliberate over representation of African countries); (4) a mix of high-, medium-, and low-income countries; (5) a mix of those that benefit from the support of the Global Fund to Fight AIDS, Tuberculosis and Malaria; the President’s Emergency Plan for AIDS Relief (PEPFAR); and other major sources of HIV funding; and (6) importantly, those whose information was readily available from published documents and Web sites. The resulting convenience sample provides a general picture of how, under different circumstances, countries incorporate human

---

aThe eight MDGs range from halving extreme poverty to halting the spread of HIV/AIDS (Goal 6) and providing universal primary education, all by the target date of 2015. See http://www.un.org/millenniumgoals/.

bThe 2001 Declaration of Commitment signed by the 189 UN members present at the UN General Assembly Special Session on HIV and AIDS details all the targets and the milestones the members should reach by 2010. Several of these are specifically concerned with human rights. See http://www.un.org/ga/aids/coverage/FinalDeclarationHIVAIDS.html.

cThe political declaration resulting from the 2006 UN General Assembly Special Session committed to set in 2006, through inclusive, transparent processes, ambitious national targets, including interim targets for 2008, in accordance with core indicators recommended by UNAIDS and affirmed the urgent need to scale up significantly toward the goal of universal access to comprehensive prevention programs, treatment, care, and support by 2010, as well as to set and maintain sound and rigorous monitoring and evaluation frameworks within national HIV/AIDS strategies. Human rights are specifically referred to in Articles 11, 29, and 31. See http://www.ua2010.org/en/UA2010/Universal-Access/Official-Papers/Political-Declaration.

dComprehensive reviews of progress toward achieving universal access were to be presented to the UN General Assembly in 2008 and 2011. One hundred thirty-two countries had submitted progress reports by January 31, 2008, the deadline for countries to submit 2008 universal access progress reports to UNAIDS. These reports are based on a set of 25 core indicators laid out in guidelines provided by UNAIDS.
Multiyear national HIV strategic planning documents were systematically examined for their inclusion of rights-based language and concepts. These documents were chosen because they provide the framework for annual or biannual operational plans.

The full list of documents reviewed is included at the end of this chapter. Drawing on the core human rights principles noted in the key components of a rights-based approach, the following keywords were searched: human rights, rights, stigma, discrimination, participation, and vulnerable groups. The following words related to goods and services in relation to the right to health were also searched: quality, availability, accessibility, access, and acceptability. The choice of keywords reflects the recognition that documents may not refer to human rights explicitly but may contain core contents of human rights norms and standards (e.g., nondiscrimination) or qualify “access” in ways that are consistent with these norms and standards. When any keyword was found in the documents reviewed, a special focus of attention was devoted to understanding the meaning of the word in context. All documents were also read for reference to core components of human rights that might have used words different from the keywords chosen for the search.

The majority of NSPs were originally published in languages other than English, and as such were searched using the English language translation, creating some uncertainty as to the correlation between the English keywords searched and their actual meaning in the original versions. When several documents of apparently equivalent significance were available for a single country, the most recent document was chosen.

Reviewers compiled their findings, and annotations were then entered in tabular form to indicate whether the keywords were present (Yes) or not (No) in the documents reviewed. Efforts to distinguish between rhetorical and operational use of these terms were made, but with limited success for reasons described later in this chapter. Table 1 summarizes the use of these terms in each NSP analyzed. The information that follows is a summary of key findings emerging from the document review, organized according to the key search terms.

**Universal Access**

Specific references to “universal access” in national plans vary according to their date of creation. The NSPs from Brazil and Nigeria predate the 2006 launch of the universal access initiative, but nonetheless use the term in relation to HIV treatment. Of those created after 2006, all countries except China use the term explicitly.

**Human Rights and Rights**

The majority of documents reviewed specifically refer to “human rights,” including those from countries that are party to most or all of the international human rights treaties (e.g., Botswana, Brazil, Germany, India, Kenya, Nigeria, Pakistan, Peru, and South Africa), as well as several that are not (e.g., Indonesia, Myanmar, and Papua New Guinea). China, even though it has ratified several international human rights treaties, avoids this language completely but gives different levels of attention to selected rights concepts, as noted in the keyword discussions that follow. A more detailed analysis of NSPs points to differences across countries in the ways core contents of human rights are referred to. For example, the plans of some countries present human rights as an overarching set of commitments with a direct reference to the right to treatment and care (e.g., Germany, India, Nigeria, Pakistan, and South Africa), while other countries’ plans refer to human rights without explicitly...

</table>
establishing access to treatment as a human right (e.g., Botswana, Indonesia, Papua New Guinea, and Peru).

**Stigma and Discrimination**

Even though the words *stigma* and *discrimination* represent two different concepts that are best addressed through different types of mechanisms, they are not clearly distinguished in the plans under analysis. Stigma reduction (through efforts toward attitudinal change in the population and among service providers) and nondiscrimination (which puts an obligation on states to take legal, policy, and programmatic measures to prevent the violation of human rights and create accountability and redress mechanisms) are not well clarified in these plans. Actions specified to reduce stigma and discrimination commonly consist only of the provision of information and education to the general public and, at times, to specific professional groups, such as the military. In several countries’ plans (e.g., Myanmar and Vietnam), there is also mention of the need to ensure confidentiality and privacy in order to prevent stigma and discrimination against people living with HIV. Less frequently, references are made concerning how the addressing of human rights abuses that result from stigma and discrimination will form part of national laws, policies, and programs.

**Participation**

While international guidance on HIV/AIDS programming calls for the participation of affected communities, participation remains an elusive concept in many NSPs. The need to include communities in consultation and governance is often stated, but little or no attention is generally paid to the specific participation of different affected communities, the mechanisms of their involvement, and/or the extent and quality of their participation. Mention of participation is entirely absent in a surprisingly high number of NSPs (e.g., those of China, India, Nigeria, Papua New Guinea, and South Africa). A list of those expected to meaningfully participate in consultation and governance and discussion of how principles of mutual accountability will be implemented are seldom specifically addressed. In several countries’ NSPs (e.g., Botswana, Brazil, Germany, Indonesia, Kenya, Myanmar, Pakistan, and Vietnam), participation by stakeholders, including people living with HIV, is noted generally even though groups are not explicitly named. Peru’s NSP is an exception; it names specific “vulnerable” groups, including adolescents, sex workers, people living with HIV, men who have sex with men, and drug users.
that should be included in relevant processes. Even when the need for participation of certain groups is noted, mention of specific affected communities, mechanisms for their involvement, and requirements (i.e., the extent and quality of their participation) is often absent.

**Attention to Vulnerable Groups**

The need to devote attention to “vulnerable groups” is commonly reflected in NSPs by way of a list of populations thought to be at greatest risk of not accessing prevention, care, and treatment. Little attention is paid, however, to the extent, comprehensiveness, and quality of services that would match the specific needs of these groups. Despite such shortcomings, the use of this language does represent a step forward in the global response. Of particular note is that all NSPs reviewed refer to sex workers (or sex work), injecting drug users, and men who have sex with men as populations in need of special attention. The mere acknowledgment that such populations exist in every country is a departure from the denial that characterized many countries during earlier stages of the pandemic.\(^{34,35}\) Additionally, some plans include women, young people, children, and uniformed personnel in the “vulnerable groups” category. Refugees, internally displaced persons, prisoners, or populations suffering from mental and other disabilities are mentioned less often despite their often unmet needs, high vulnerability to HIV infection, and susceptibility to human rights abuses.\(^{36,37}\) (Germany is an exception in that its NSP clearly recognizes the vulnerability of migrants and prisoners.)

Generally speaking, a clear effort has been made to consider vulnerable populations in NSPs according to a scale of risk and needs. Reviews of operating plans, however, suggest that even when certain populations are identified as being vulnerable, the priority afforded to them in actually accessing needed prevention, care, and treatment is not supported by a greater share of available resources. Typically, the main focus of national efforts was found to be the general population or young people, even in countries where the epidemic remains concentrated in highly vulnerable populations (e.g., China, India, Indonesia, and Vietnam). In the NSP for Papua New Guinea, “high-risk groups with high-risk vulnerability” are noted in the glossary but without reference to specific populations. This plan also includes a warning against identifying specific populations (as opposed to specific behaviors), as this may “exacerbate stigma and discrimination.” The plan does not, however, indicate how the recognition of such behaviors can help in targeting populations in need of specific services and support.

**Availability**

The availability of services and goods is explicitly noted in all NSPs, with the exception of Germany’s, where the brief mention of availability presumes that services are guaranteed to all through existing health systems. In general, NSPs refer to availability in a variety of ways, including limitations to availability, reasons for limited availability, inequity in availability, and the need to scale up availability through system strengthening (and, in some situations, through reductions in the price of procured commodities, such as antiretroviral drugs [ARVs]). Language often focuses on antiretroviral therapy (ART), with little attention paid to prevention or care more generally. Some countries (e.g., Botswana, Brazil, Kenya, Myanmar, Nigeria, Pakistan, Peru, South Africa, and Vietnam) are very explicit about policies and strategic approaches to ensure the availability of HIV-related structures, services, and goods. Others (e.g., China, Indonesia, and Papua New Guinea) refer only to low availability of goods and services in the context of barriers to ART, expressing a commitment to improve access but without proposing specific
strategic approaches. India proposes to address unequal availability through research and development. Overall, the NSPs reflect countries’ concerns about the availability of infrastructure, services, and goods but offer little indication of how the availability of these resources is to be ensured generally or for the particular benefit of marginalized populations. This lack of clarity may reflect the inability of national programs to guarantee availability, since they are dependent on external resources that are allocated only once a strategic plan is in place.

**Accessibility**

Access is the mainstay of all NSPs, but the use of the term varies across countries and even within most national plans. The variable use of this term raises the question of whether there is a connection between the rhetorical use of the word and its practical implications. Commonly, the term *access* is used specifically in the context of ART and, to a limited degree, in relation to other components of prevention, treatment, and care (e.g., preventive services such as sexually transmitted infection programs or commodities, such as condoms). That said, China, Myanmar, Papua New Guinea, and Vietnam all include mention of accessibility concerns in relation to VCT; China and Vietnam also refer to access to condoms.

General goals to enhance access for all people living with HIV are occasionally noted in the NSPs, but there are wide variations among the specific targets named. Reference is sometimes made to specific subpopulations, such as pregnant women, or subnational regions (e.g., certain districts in Botswana), but categories of most-at-risk populations are seldom mentioned. In fact, Vietnam and Peru are the only two countries in the sample to mention specific vulnerable subpopulations of concern. Vietnam’s NSP identifies the need to increase access for sex workers, drug users, street children, working young people, school dropouts, disabled young people, ethnic minority young people, and “other groups.” Peru’s NSP specifically mentions access by adolescents, sex workers, drug users, and men who have sex with men. Some countries (e.g., Botswana) also refer to specific access plans when describing the decentralized and progressive roll-out of treatment. The same limitation mentioned earlier, that NSPs are often formulated before resources to support them are secured, may apply here as well.

**Acceptability**

The concept of acceptability is not commonly incorporated into NSPs. In our review, the parameters used to define the concept of acceptability were extended to include NSPs that were sufficiently explicit about ways in which the most vulnerable populations should be served—including attention to their specific needs and environments, and to human rights abuses to which they might be exposed. Even with this extension of the concept, acceptability is mentioned by only a limited number of countries (e.g., Botswana, India, Pakistan, Papua New Guinea, and South Africa) and in very different ways. In some NSPs (e.g., those of India and Papua New Guinea), acceptability is equated with creating HIV interventions that are culturally acceptable; other countries use the word *acceptability* in relation to the more general goal of ensuring that STI and HIV interventions are accessible, affordable, and acceptable (e.g., Botswana and Pakistan). Finally, in the case of South Africa, the term *acceptability* is used in the context of standards for laboratory testing. In the few cases where acceptability is noted, there is no apparent consideration of policies or other measures within and outside the health sector that could help make services socially, culturally, or otherwise “acceptable.”
Quality

Quality is referred to in two distinct ways in the NSPs: with regard to ensuring quality of life and to ensuring quality of services and goods. While both types of quality are important elements of a sound response to HIV, in the majority of NSPs references to quality of life tend to overshadow the mention of quality as it relates to goods and services. Descriptions of standards of prevention, care, and treatment are usually missing from the NSPs; instead, general references are made to ARVs, ART, or prevention of mother-to-child transmission of HIV (PMTCT) as stated entitlements. Myanmar and Kenya mention the need to ensure quality of blood stores, but the NSPs lack specific information about how this is to be achieved. Germany (the only member country of the Organization for Economic Cooperation and Development [OECD] included in the analysis) is the only country to mention quality assurance systems and the need to ensure the quality of generic medicines. Even though NSPs are not necessarily the best place to include such standards, it is worth noting that few NSPs are explicit about the types and quality of treatment for which people living with HIV or people with STIs are eligible, or how quality standards will be set, monitored, and periodically reevaluated. The prevailing uncertainty regarding long-term financing of ART in low- and middle-income countries and, in some cases, the absence of national quality control and quality assurance schemes may be among the reasons for this lack of clarity.

Discussion

The congruence between commitments to achieving universal access and human rights was widely recognized by the countries selected for this review, regardless of their geopolitical characteristics and overall human rights records. This indicates that attention to human rights exists in HIV-related national strategy documents regardless of whether or not the country concerned is party to most international human rights treaties or enshrines human rights in its national legislation. This pattern likely reflects a general acceptance by countries of the relevance of human rights norms and standards to national HIV responses, as well as the fact that this language has become part of the global discourse regarding HIV.

Despite the widespread incorporation of human rights language in these documents, the rhetoric is seldom translated into strategic guidance on how, by whom, and for whom human rights principles will be respected, protected, and fulfilled. Comparisons between NSPs and operational plans generally reveal the gaps between rhetoric and intended practice; while statements on human rights are commonplace in strategic documents, their translation into operational terms or inclusion as part of monitoring frameworks is most often deficient or absent.

Overall, among the countries reviewed, it appears that national strategic documents contain many of the ingredients of a rights-based approach to HIV. Yet this approach is not incorporated into strategies in a systematic way. Additionally, a human rights analysis of the NSPs highlights the fact that certain approaches, such as legal reform, ensuring confidentiality, preventing violence against women, and caring for orphans and other vulnerable children, are still not receiving sufficient attention. This oversight is at odds with the UN political declaration and guidance extended by international institutions.12 Taken together, these findings can help point to ways in which common obstacles to achieving universal access can be overcome.

A further review is needed to determine whether related policy and legislation within these countries is consistent with the pronouncements made, or whether they serve as obstacles to an effective response (for instance, by requiring parental consent for access to HIV prevention...
suggests that, in most countries, access seems to be primarily associated with treatment and that more emphasis is needed on access to prevention as well as support. The growing imbalance resulting from the limited availability of national resources in low- and middle-income countries and the increasing availability of international HIV/AIDS funding makes national programs increasingly dependent on external support. This has potentially significant implications for the share of resources and commitments in NSPs that are allocated to treatment and care. Furthermore, while much attention is paid to the provision of treatment services, structural interventions that lie beyond the traditional domain of the health sector, such as strategies to reduce gender inequality, are mostly absent from NSPs. Additionally, constraints that may be linked to the acceptability of services were insufficiently dealt with in all the NSPs reviewed, in which the “one size fits all” approach to the provision of services commonly overlooked the specific needs and capacities of targeted populations. Taken together, these findings reveal a great deal about the ways in which national policies and programs succeed or fail in sufficiently addressing the obstacles (whether social, legal, or other) their populations may experience in accessing essential HIV-related services.

CONCLUSION
The findings of this review stress the need for governments to be more explicit about the congruence between their strategic approach to achieving HIV prevention, care, and treatment goals and the human rights norms and standards to which they are committed. Too often, the rhetoric of human rights included in national strategic documents is static, with little description of how, to what extent, and for whom human rights will be considered in the context of national care and treatment efforts. It is possible that if those countries reluctant to use human rights terminology in their NSPs were more informed and services or by criminalizing sex work or same-sex partnerships). Such a review could help ensure that the inclusion of human rights language in national documents reflects more than simply the fact that this language is part of the global discourse regarding HIV.

The reluctance on the part of many countries to explicitly name human rights concepts or approaches raises concerns about the accountability of state and nonstate actors in the context of HIV prevention, care, and treatment. This reluctance may denote uncertainty on the part of countries regarding their ability to comply with human rights standards. Some countries—regardless of their level of income—may fear that any explicit statements would be interpreted or misinterpreted as an obligation to give everyone immediate and full access to the needed services, including costly treatments.

Time-bound plans of operation are generally more explicit than NSPs about coverage and comprehensiveness of treatment in relation to set targets. One conclusion that can be drawn from this finding is that NSPs generally tend not to commit to particular levels of coverage until financial resources have been secured, perhaps reflecting the tendency of these plans to be donor-driven and/or dependent on national financing cycles that may be out of sync with the time periods covered by the NSPs. Another possible conclusion is that operational plans are crucial instruments in the planning process that are often developed wholly or partly separate from the NSP; once resources are in place, these documents may be the key to implementation and accountability. Yet operational plans are often developed late in the process, lack specifics, and are inconsistent with the general priorities set out in NSPs. This may be another result of the donor-driven, rather than need-driven, nature of many HIV responses in low- and middle-income countries.

Despite the fact that the call for universal access targets both prevention and treatment, this review
Human rights have been central to the HIV response ever since the emergence of the pandemic. While new technologies are needed to bring HIV under control, technologies alone are not sufficient. Vast resources are needed to sustain and further expand access to prevention, care, and treatment, but resource availability cannot be allowed to drive the response to HIV. Beyond theory and semantics, human rights bring *human* values into the equation while establishing a vision of greater justice, fairness, and dignity as fundamental to the success of the response to this global pandemic.

REFERENCE LIST

THE HUMAN RIGHTS OF WOMEN ARE enshrined in the Universal Declaration of Human Rights that was adopted and proclaimed by the United Nations General Assembly in 1948. However, prevailing traditions; individual and societal prejudices; and social, economic, and political interests have converged to marginalize women from becoming equal beneficiaries of the current definitions of “general” human rights and to relegate them to secondary and/or "special interest" status within human rights considerations. The fact that women are not able to expect equal rights is largely a reflection of the persistent but often pervasive levels of existing gender inequalities, which exert formidable negative impacts on their lives. Human rights abuses generally affect women and men differently. Gender inequality manifests in power imbalance in sexual relations, as well as the discriminatory practices that women face in employment, education, access to resources and services, and other important spheres of their daily lives. Discrimination against women impacts beyond their own lives, and affects their ability to protect, support, and care for their families and to participate effectively and equitably in community life. Rights abuses and gender inequality intersect with HIV/AIDS and are fueling the spread of the epidemic. HIV/AIDS-related discrimination is most felt by those who are assumed to be at risk because of their behavior, class, gender, race, or sexual orientation, and women largely are worse off than men when these factors are considered.

During the 1980s, a great deal of attention was paid to upholding the human rights of people living with HIV. This resulted in a more informed understanding of the importance of human rights in determining not only vulnerability to HIV infection, but also the likelihood of accessing relevant care and support by those who are infected. It became apparent that the realization and protection of rights was critical in reducing vulnerability to infection and protecting those infected with and affected by HIV/AIDS. With respect to women and girls, several key strategies have been promoted to address their rights in the context of HIV/AIDS, including the advancement of women’s full enjoyment of all human rights; the promotion of shared responsibility between men and women to ensure safe sex; and the empowerment of women to have control over and decide freely and responsibly on matters related to their sexuality, to enhance their ability to protect themselves.
Consensus on the roles and responsibilities of governments have been largely driven and articulated through several international conferences addressing gender inequality, as well as the link between gender and HIV/AIDS. These international conferences include the International Conference on Population and Development, held in Cairo in 1994, which emphasized the need to “promote gender equality in all spheres of life, including family and community life, and to encourage and enable men to take responsibility for their sexual and reproductive behavior and their social and family roles”; and the Beijing Platform for Action (Fourth World Conference on Women, 1995), which affirmed the principle of shared responsibility between men and women. Following the Beijing Conference, the UN General Assembly mandated the Commission on the Status of Women to integrate a follow-up process within its program to review the critical areas of concern in the Beijing Platform for Action and to catalyze the mainstreaming of gender in United Nations activities.

More recently, the 2001 UN General Assembly Special Session on HIV/AIDS (UNGASS) stressed the need to challenge gender stereotypes and attitudes and gender inequalities in relation to HIV/AIDS. The UNGASS declaration endorsed by several governments explicitly states that gender “equality, and the empowerment of women are a fundamental prerequisite in the reduction of the vulnerability of girls and women to HIV/AIDS.” Setting specific targets for action, the Millennium Development Goals, signed by 198 countries and major development institutions, adopted benchmarks for women’s rights and empowerment and for containing the spread of HIV.

However, despite the call for national governments and international donors to overcome the obstacles to scaling up HIV services, including addressing gender inequalities that impact on the epidemic, many governments have struggled to respond. It is largely acknowledged that limited resources and several other constraints make it difficult for governments to fulfill their obligations to ensuring gender equality and the human rights of citizens, especially those vulnerable to, living with, and affected by HIV. In real terms, the presence of laws and policies has not adequately curtailed the abuse of women’s rights or the levels of their vulnerability. The successful implementation of rights-based laws, policies and programs affecting women depend on how these are viewed and received by those from whom women experience the most serious gender inequities—family and community members. Thus, in order to achieve women’s human rights—a prerequisite for women’s empowerment—and to impact on HIV/AIDS, it is necessary to implement complementary and interrelated bottom-up, broad-based strategies targeting all segments of the community rather than those that focus primarily on women.

WOMEN AND HIV/AIDS

Examining the situation of women and the HIV epidemic provides the basis for understanding the link between the epidemic and women’s rights issues. Generally, the epidemic has largely flourished in the most affected regions because women and girls have limited means and power to protect themselves—and vulnerability to HIV results from the lack of power of individuals and communities to reduce or manage their risk of exposure to HIV infection. Once infected, women and girls have limited means and power to access the care and support they need. HIV/AIDS vulnerability is gender-biased and mediated by factors that are largely out of women's control. These factors include gender-based violence, imbalance in sexual power relations, unequal access to rights, discriminatory laws and policies, traditional norms and practices, poverty, and poor access to services. For
very vulnerable subpopulations of women such as sex workers, their level of vulnerability is increased by being women as well as by engaging in an economic activity that exposes them to greater social, sexual, and physical abuse and to increased risk of HIV infection.

Increasingly, women all over the world are disproportionately affected by HIV. Sub-Saharan Africa is the region of the world most severely affected by the virus, and within this region its effects are most experienced by young women. The commonly held notion is that in Africa, HIV/AIDS has the face of a woman. The key features of the feminized African epidemic include the young age at which infection peaks in females compared with males, high-female-prevalence rates, high risk of transmission from mother to child, and the huge burden of AIDS-related care carried by women. Gender inequities and the lower status of women are largely at the root of women’s vulnerability to infection in sub-Saharan Africa and the disproportionate burden they bear. A 2007 study by the U.S.-based Physicians for Human Rights conducted in Botswana and Swaziland assessed the factors contributing to HIV infection and concluded that discrimination against women was spreading HIV. In both countries, the legal system accords women a lesser status than men and restricts several rights such as ownership of property and inheritance, among others. This situation is borne out of widespread cultural beliefs that perceive women to be inferior to men.

According to the Joint United Nations Program on HIV/AIDS (UNAIDS), globally 48% of people over the age of 15 who are living with HIV are women, and 76% of all HIV-positive women live in sub-Saharan Africa. In this region, women make up 59% of all adults living with HIV. The severity of the epidemic among women is related to the degree of gender inequality and their low social status. The view that women have the power and choice to protect themselves is not a realistic one in many parts of the world, particularly in sub-Saharan Africa. The South African situation starkly captures the particularly disproportionate vulnerability of young women and their limited power to protect themselves. National surveys of 15- to 24-year-olds showed that young women make up 77% of the 10% of people living with HIV nationally; and 16% of 15- to 24-year-old females were HIV-positive, compared with 4.8% of males in the same age group.

Socially endorsed discriminatory practices and inequities against women result in HIV-related repercussions. These not only contribute to women’s poor access to services and ownership of vital economic livelihoods and assets, but also curtail the extent to which women can seek their rights or advance their self-determination. Women’s lesser power in negotiating sexual relations and safer sex and in protecting themselves against gender-based violence, as well as their limited access to reproductive health services, underpin the slow progress in reducing their vulnerability to HIV/AIDS. For example, serious violations of rights involving rape and sexual assault against women are often underreported, mainly due to women’s fear of stigma and further repercussions, as well as apathy resulting from the often poor performance of the criminal justice systems in such cases.

Research from several countries has shown that sexual violence by men and the HIV vulnerability of women are linked. In the United States, for example, women in violent and abusive relationships are less likely to use condoms and are more likely to have sexually transmitted infections than those who have not experienced violent relationships. With specific reference to HIV infection, a study conducted in Kigali, Rwanda, found that HIV-positive women had a history of experiencing more unwanted sex than those who were not, suggesting an association between sexual assault
and HIV infection. Violent sexual behaviors by men can also impact negatively on themselves. A recently reported study in South Africa showed that men with a history of sexual assault were at significantly higher risk for HIV transmission than those who were nonassaultive. Men with a history of sexual assault were also more likely to endorse hostile attitudes toward women and to accept violence against women, although these attitudes and beliefs were common among men with or without a history of sexual assault.

South Africa’s Medical Research Council reported in 2004 that every six hours a woman is killed by her intimate partner, and conviction rates for charges of domestic violence and homicides are no higher than 37.3%. Only one in nine victims reports rape, and fewer than 10% of reported rapes lead to conviction. It has also been shown that women subjected to violence have up to three times greater risk of acquiring HIV infection. A 2007 research study reported a prevalence of 15.2% among 21-year-olds reporting one lifetime partner and 28.5% among those reporting more than three lifetime partners. These results suggest a much higher rate of male-to-female transmission than was previously acknowledged. These high levels of HIV infection in young women question our understanding of gender-related risks and the relevance and effectiveness of current prevention strategies in contexts where sexual violence and coercion, denial of women’s rights, and poor access to services place women at a heightened risk of infection.

Generally speaking, the vulnerability of women is contextually and behaviorally linked with gender and power norms that accord to men and boys a superior status and greater rights. While cultural, social, and economic factors offer men the privilege of having multiple sexual partners, society prescribes abstinence and fidelity for women. Girls are expected to maintain their virginity before marriage, but the same standard is not stipulated for boys. Virginity testing is being used in certain communities to assess how girls measure on this score, and despite the accompanying violations of rights, supporters of virginity testing continue to ignore the manner in which it is worsening the already low status of girls and exposing them to increased risk. Also, intergenerational liaisons between older men and young women, often facilitated by economic and social pressures, are condoned in many African societies. These contradictions explain to a large extent the high vulnerability of young women to HIV.

REDDUCING WOMEN’S VULNERABILITY TO HIV/AIDS

From a gender perspective, HIV/AIDS intersects at several levels and in many ways with the social injustice and oppression women suffer. Women have limited power to access their rights because of conflicts with traditional and cultural concepts of the place of women in society. Programmatic and policy responses to address HIV/AIDS need to take cognizance of this fact. Social change is required to create the atmosphere for women’s rights to become ingrained in the fabric of society and for these rights to be enforced. HIV/AIDS interventions that aim to impact on women should embrace social, human rights and cultural aspects to complement and strengthen behavioral interventions that otherwise will have limited application in the lives of vulnerable women.

With the recognition that men’s gender-related attitudes and their sexual behaviors are at the core of the HIV epidemic in most regions of the world, several programs are promoting interventions involving men and boys to transform and influence gender norms and risky sexual behaviors. These programs focus on promoting individual and group transformation of boys and men and also seek to influence broad-based community attitudes
and norms around gender equity and domestic violence. Other interventions have promoted the involvement of men in support of prevention of mother-to-child transmission (PMTCT), voluntary counseling and testing, maternal health, and care and treatment services. As shown in this chapter, it is evident that community-based programs involving men are providing the space for positive engagement to take place on issues around gender equality and male sexual norms, and for women’s human rights to be discussed and addressed.

**Promoting the Involvement of Boys and Men**

The Men As Partners (MAP) program, pioneered by EngenderHealth, recognizes the vital role that men can play in promoting gender equality, reducing violence against women, and advancing women’s reproductive health and rights. The MAP program has been implemented in over 20 countries. In South Africa, MAP has focused on challenging attitudes and behaviors that are held by men that compromise their own health as well as the health and safety of women. The evaluation of the program showed that men’s perceptions on according women the same rights as men and on gender-based violence changed positively.29

Instituto Promundo in Brazil and Community of Resource Organization (CORO) Literacy in India, in conjunction with the Population Council, an international nongovernmental organization based in the United States, have conducted interventions aimed at changing negative aspects of masculinity and reducing risky sexual behaviors among men. These programs combined group education with a community-based and gender-focused “lifestyles” social marketing campaign to reinforce gender-equity and HIV-prevention messages and promote violence-free and gender-sensitive lifestyles for young men. The results showed that participants were able to transform and change their support for inequitable gender norms and sexual harassment, and they adopted more protective behaviors.30 The Medical Research Council’s evaluation of the Stepping Stones program implemented in rural parts of the Eastern Cape Province of South Africa to build more gender equitable relationships also showed that men who participated in the program reported fewer sexual partners and improved communication between partners.31

Similarly, a program in Zambia to address the inequitable involvement of men and boys in community care and support services trained and supported boys and girls to take part in community home-based care activities and HIV prevention. The results showed that there was no difference in the level of participation and the types of care and support services males and females provided. In addition, males were less likely to perceive girls to be responsible for spreading HIV, and they showed a better level of appreciation of their risk to HIV infection.32

**ADDRESSING THE PREVENTION, CARE, AND TREATMENT NEEDS OF WOMEN**

Empowerment ought to be a critical outcome of all programs addressing HIV/AIDS, especially those that focus on women and girls. Empowerment issues for HIV-positive and negative women can be unique as well as overlapping. HIV-positive women, for example, may experience more stigma and rejection than their male counterparts, and gender-based stigma constitutes a serious form of disempowerment for women and can deter access to services. Stigma can result from activities and policies to address prevention and care for women, such as in formula feeding of infants born to HIV-positive mothers, the use of voluntary counseling and testing services, and disclosure of HIV-positive status; and women can experience stigma and
“WE CAN CHANGE THINGS AS MEN”: EMPOWERING HIV-POSITIVE MEN TO PLAY CONSTRUCTIVE ROLES IN THEIR FAMILIES AND COMMUNITIES

The following excerpt was written by Manoj, a 25-year-old, HIV-positive man from Gujarat, India. The EngenderHealth Men As Partners (MAP) program helped him gain new insights about being a man. Now he counsels other men about taking responsibility and is forging his own path in life.

I learned that I was HIV-positive when I donated blood for a friend’s operation. At first I couldn’t talk to anyone. I wanted to kill myself. But at the hospital, a counselor told me, “You have one chance to live this life, and you can live it as much as you want.” She took a great burden off of my heart. I later became a counselor with the Gujarat Network of Positive People (GSNP+) because I wanted to help others like she had helped me.

Through my experience as a counselor, I’ve learned the importance of working with men. A man can talk to his family and make a message clear to them because he is seen as the leader and the decision maker. And men need to know that they are not alone in the problems that they face. So when EngenderHealth partnered with GSNP+ to bring their Men As Partners program to Gujarat last year, I was eager to participate.

I have attended several MAP trainings and workshops. They are conducted in a very understandable way, and the topics and examples are relevant to our everyday lives. It helped me to start thinking more carefully about my everyday behavior. For example, I used to automatically ask my sister to get me water. Why shouldn’t I be the one to bring her water?

The MAP trainings also make me a better counselor. I learned practical information about positive and healthy living that I can share with my clients. Now I find it easier to talk to men about sex and about how you can be a man without engaging in risky behaviors, like having multiple partners. I tell my male clients that it is our responsibility to wear condoms and prevent spreading the virus. Taking responsibility is an important lesson that I’ve learned from MAP. When I talk to my male clients about MAP, one of the first things I tell them is that as men we can help improve the health of our families, friends, and community, and that is why they should join the program.

The MAP program has also helped me to make important personal decisions. I have a girlfriend; she is also HIV-positive and a counselor. She is a widow and has a six-year-old son. Before, I could not see a future for us because of society’s prejudice against widows and second marriages. But I learned that these ideas are simply creations of society, and I do not have to
adhere to them. My girlfriend’s son is now my son, and we are hoping to get married. I am following my heart, thanks to MAP.

I also decided to tell my family that I am HIV-positive, after years of hiding it from them. Like many others who are living with HIV, I was afraid. Recently I invited them to a World AIDS Day MAP event, where I spoke about living with HIV. My family was crying, but I knew that it was because they were proud of me. My family is so supportive, and when they see me working passionately for something that I care about, that is enough for them.

blame for providing care to an infected spouse or child. Despite this knowledge, few programs for women take adequate measures to prevent stigma and to empower women to overcome or cope with stigma. Programs focusing on women and girls have traditionally tried to get them to change their behavior, acquire skills for caregiving, and access PMTCT and treatment services.

An example of a program that has attempted to develop strategies in response to these issues is the mothers2mothers program in South Africa, an innovative program that aims to reduce mother-to-child transmission, destigmatize HIV, and empower women through a peer approach in which trained HIV-positive mothers provide psychosocial support to HIV-positive pregnant women. Results from the program showed that this peer approach was successful in facilitating the transfer of information, disclosure—particularly to partners—uptake of PMTCT, better PMTCT outcomes, and access to treatment and psychosocial well-being.33

Various female-controlled prevention methods have been piloted, including the female condom. The introduction of the female condom in 1994 was seen as an opening for women to have a tool in their hands to reverse the power imbalance in heterosexual relationships and to protect themselves from HIV and sexually transmitted infections as well as unintended pregnancy. Despite evidence to show the protective value of the female condom and its role in empowering women to negotiate safer sex, it still needs to be fully incorporated into national strategies to expand women’s choices for dual protection.34 Research into the development and testing of microbicide products to prevent HIV infection among women and among HIV-discordant couples continues to receive great attention and support for its potential value as a female-controlled method. Offering women more
effective preventive methods needs to remain a priority, especially those that can be used by women who are unable to negotiate use of the male condom.

Evidence shows that married women, in particular married adolescents, are at great risk of HIV infection. In Africa and Asia, 50% to 60% of girls get married by the time they are 18 years, often to older, more sexually experienced men. Studies have shown that married adolescent girls tend to have higher rates of HIV than sexually active unmarried girls. In rural Uganda, 88% of HIV-positive women aged 15–19 years were married, and in Kisumu, Kenya, and Ndola, Zambia, the rates were 48% and 65%, respectively. The vulnerability of married adolescents is linked to several factors, including poor education, limited peer networks, restricted social mobility, unprotected sex with older male partners, limited access to information, limited autonomy, and increased risk of gender-based violence.

Several strategies have been used to address married adolescents’ vulnerability in countries such as Bangladesh, India, Burkina Faso, and Ethiopia. These include developing safe spaces for girls; providing incentives for girls and their parents to delay marriage; removing obstacles to girls’ enrollment in school and fostering retention; increasing girls’ access to economic skills and resources; and working with parents, religious leaders, and community members to increase awareness of the need for girls to delay marriage.

Challenges around targeting HIV-positive people include fear of victimization and stigmatization, and concerns around the complex ethical issues involved. However, there are very compelling reasons for considering prevention activities that meet the particular needs of people with HIV. Among several reasons, positive prevention interventions provide the opportunity to address the gender relations and power dynamics between women and men. These become even more critical when one or both partners are living with HIV. For example, women who already have little decision-making power in a relationship may face increased levels of social exclusion, abandonment, and violence if they disclose their positive HIV status.

Gender inequities in access to treatment have been bridged considerably. Out of 30 countries for which data was available on the “3 by 5” initiative, 20 showed that women were accessing treatment equitably, but there are concerns that women may have more challenges adhering to treatment. Women’s fear of violence may be a serious barrier in access to treatment. A clinic in Zambia showed that 60% of women eligible for antiretroviral therapy opted out because they were concerned about violence and abandonment by their partners if they disclosed their status. In terms of the prevention of transmission to infants, only 9% of pregnant women in low- and middle-income countries were being offered PMTCT services. On the positive side, PMTCT programs are increasingly being utilized as a conduit to broaden the continuum of care for HIV-positive mothers and pregnant women and to implement a family-centered approach to prevention, care, and treatment, thus reducing the threats HIV-positive mothers may face at the family and community levels.

**Focusing on Socioeconomic Empowerment of Women**

Unfavorable global and national economic policies, the impact of war, natural disaster, drought, and famine are weakening women’s socioeconomic status. This, coupled with existing gender-biased cultural practices that deny women access to property, resources, inheritance, and autonomous means of livelihood, compromises their ability to prevent and cope with HIV/AIDS. Women’s right to own property and land is unequal to that of men in many parts of the world. This includes the right
to own, inherit, or dispose of property as well as unhindered access to land for farming and to other natural resources. In Kenya, for example, women constitute 80% of the agricultural labor force but only own 5% of the land. Other common rights violations in the context of AIDS in Africa include evicting AIDS widows and their children from their homes and loss of farmland and other tangible assets to relatives.

Although research evidence is inconclusive on whether a higher socioeconomic status protects against HIV infection, there is a widespread assumption that increasing the economic assets of women and girls can play an important role in HIV prevention. Direct evidence of the link between HIV risk and poverty was seen in a South African study conducted in the province of KwaZulu-Natal that showed that poorer women were more likely to have an earlier sexual debut, a nonconsensual first sexual encounter, and higher rates of forced sex. Details of the study show that risky behaviors among this group included greater likelihood of exchange of sex for money, goods, or favor, and a higher number of sexual partners. Microfinance programs have been adopted in many countries to help poor women secure a degree of economic independence, and when integrated with HIV/AIDS interventions, these programs constitute a viable strategy for addressing HIV and poverty. Examples of programs combining microfinance and HIV include those by World Vision, which has successfully linked HIV education with microfinance, involving groups of 20–30 women.

Women could lose their property and assets when the death of their spouse is perceived to be due to AIDS or when they are perceived to have AIDS. They also experience stigma and rejection and sometimes are evicted from their homes. The loss of vital assets and channels of support puts widows and their children at even greater risk of infection and curtails the likelihood that they will be able to survive. Grassroots organizations and legal professionals in countries such as Kenya, Rwanda, Zambia, and Zimbabwe have responded to these challenges by training community para-legals, village chiefs, and members of land boards about women’s property, inheritance, and legal rights. They also help women overcome ignorance about issues like how courts function and how to write a will, and help them to obtain and safeguard important legal documents.

The burden of care for people living with HIV is borne largely by women, often poor, older women who have no economic resources and who are also likely to suffer from age-related chronic illnesses. In Kenya and South Africa, for example, grandmothers become parents a second time because of the loss of their own children, and are often left responsible for the care of grandchildren. Elderly caregivers go through considerable physical, emotional, and psychological pain and have poor access to social and health services and support to care for their dependents. Several initiatives are helping to reduce the care burden experienced by women. In Swaziland, the government, with funds from the Global Fund to Fight AIDS, Tuberculosis and Malaria, intends to provide financial support to caregivers who look after orphans.

**Organizing around Women’s Rights and Empowerment in the Context of HIV/AIDS**

Organizing to foster women’s rights and empowerment has involved different stakeholders and addressed several aspects of women’s subordinate status that underpin their vulnerability. Women’s rights networks have been formed globally, regionally, and nationally as well as at the grassroots level. The common purpose of these groups is the need to change the situation of women and to empower them in order to reduce their
vulnerability. Strategies adopted have included community mobilization, education, advocacy, litigation, policy formulation, service delivery and capacity building. These interventions have resulted in greater awareness of women and HIV/AIDS issues at international and local levels, in having the voices of women heard, and ensuring the allocation of resources to support initiatives that potentially impact women and girls.

The Society for Women and AIDS in Africa (SWAA), formed in 1988 by professional African women, was one of the earliest pan-African networks established across 40 African countries to recognize the potential impact of HIV/AIDS on women in the continent and to mobilize for organized action by women and communities.\(^\text{56}\) SWAA’s core purpose is to address the root causes of the vulnerability of women to HIV/AIDS and the disproportionate impact of HIV/AIDS on women in Africa. For more than 20 years, SWAA has promoted programs that address the rights of women, their access to health care, education, economic and sociocultural rights, and rights of women living with HIV/AIDS, in particular to reduce the stigma and discrimination they face. For its pioneering work and contribution in furthering the understanding of the diverse ways in which HIV/AIDS impacts on women, families, and communities in Africa and in mobilizing and galvanizing a regional platform for women to respond to the epidemic, SWAA has been recognized internationally and regionally; and its work continues to remain responsive to the needs of women, families, and communities.

In furtherance of the rights of HIV-positive women, global-level organizing by HIV-positive women started in 1992 with the formation of the International Community of Women Living with HIV/AIDS (ICW). Since then several other women’s groups have been formed in many countries to address local issues affecting HIV-positive women. The ICW seeks to provide support, information, and services to women living with HIV worldwide and to build their capacity to influence and contribute to policy development. Despite several challenges, the ICW continues to promote efforts to enable HIV-positive women to access their rights, particularly their rights to sexual, reproductive, legal, financial, and general health-care services.\(^\text{57}\)

With respect to marginalized and stigmatized groups of women, promoting their rights is more challenging. Homophobia is still a very serious problem in Africa, and African lesbians experience multiple layers of discrimination and serious physical and sexual violence because of their sexual orientation and their gender.\(^\text{58}\) However, research and advocacy work in the continent is increasing levels of awareness about the existence of homosexuals in Africa and giving momentum to efforts by gay and lesbian groups to organize around their issues, including their rights. For example, the Coalition of African Lesbians, consisting of lesbian and feminist organizations from 14 African countries, is active in ensuring that lesbian rights issues are brought to the fore.\(^\text{59}\)

In developing countries, especially in the Africa and Asia regions, female sex workers suffer high levels of stigma, discrimination, abuse, and exploitation from the community as well as law enforcement agents.\(^\text{60}\) Despite this situation, many sex workers’ organizations and programs have developed and are addressing the human rights of sex workers. The Sonagachi Project in India is a well-known example of how female sex workers have formed a strong cooperative, reaching out to about 65,000 sex workers and their children. This sex worker–run project promotes the use of condoms, runs literacy and vocational programs, and lobbies for the recognition of sex workers’ rights and for full legalization.\(^\text{61}\)
CONCLUSION

Competing demands, lack of adequate resources, and limited capacity all curtail the comprehensiveness of local and national HIV/AIDS strategies. These factors in turn limit the promotion of appropriate interventions that integrate strategies for women’s empowerment within the broader HIV/AIDS response. Where resources are scarce, the pursuit of women’s rights is often a low priority. Generally, such settings are also plagued by weak public institutions and civil society, adverse gender norms, and poverty, all of which constitute major challenges to the development of sustainable human rights environments that could potentially reduce women’s vulnerability to HIV/AIDS. For example, HIV infection or the death of a spouse due to AIDS can further compromise the rights of women, resulting in the loss of property, resources, and assets. Thus, empowerment strategies that focus on women, without including the people who have influence over their lives, could place women at increased risk because of the potential negative repercussions they could experience.

There is clear evidence from research that the vulnerability of women to HIV is linked to denial, abuse, and violation of women’s rights. Lessons from programs and policies that seek to expand the rights of women and to reduce their vulnerability to HIV/AIDS demonstrate the importance of not focusing exclusively on women, but rather addressing the roles of men, families, and communities in the subjugation of women. Although promising results have been reported from interventions that focus on men to address women’s empowerment, gender norms, and gender-based violence, these programs are currently reaching only a small proportion of men and have not developed a close working relationship with women’s rights programs.

Given the challenges women face in seeking their rights, it is more appropriate to promote grassroots women’s rights and empowerment models while taking prevailing cultural and social conditions into account. These models provide useful and relevant frameworks for action and community participation and have the potential to have a great impact while minimizing any backlash that women may experience from asserting their individual rights or mobilizing as groups to claim their rights. Women’s rights programs addressing issues such as gender-based violence could enhance their relevance and impact by combining their predominantly legal and “punitive” approaches with support and motivation for men to become primary partners and actors in promoting women’s rights. Community-based approaches to address women’s empowerment have the potential to influence and change, in real terms, women’s subordinate status and to address the internalization and acceptance of gender-based violence and other rights violations that underpin women’s vulnerability. These approaches, together with strategies that build on positive indigenous values and traditions that accord women respect in the community, endorse women’s rights, and disapprove of gender-based violence, would facilitate broad-based participation of women, men, community-based organizations, and traditional and religious leaders in efforts to empower women.

Resource-limited settings are often the ones in which HIV/AIDS is most severely experienced and where numerous social challenges and priorities hamper adequate responses. Although challenging, these settings offer several opportunities and entry points for the promotion of women’s empowerment and for addressing entrenched gender inequities. Sensitive, feasible, and practical solutions to address the factors that put women at risk of HIV infection need to be given greater priority. The fact that women, and young women in particular, continue to be so vulnerable to HIV infection despite increasing availability and allocation of resources points out the existing gaps and weaknesses in
current strategies. Generic approaches to women’s empowerment may have severe limitations; empowerment strategies for young women, for example, must be tailored to address their specific vulnerabilities to HIV. These may be different from strategies that are designed for older women, who are less threatened by HIV infection but are overburdened by care responsibilities.

Finally, sharing local, national, and regional lessons of what works with respect to reducing HIV vulnerability and promoting women’s empowerment in the context of HIV/AIDS needs to be prioritized. While international frameworks and provisions are important guidelines for action, their limited application in resource-limited settings should be addressed. Ultimately, grassroots responses stand the most promising chance of bringing about tangible and lasting advancements in the empowerment of women and reducing their vulnerability to HIV/AIDS. More resources are needed to test, evaluate, and scale up appropriate and effective interventions that truly empower women; and genuine partnership between policymakers, program managers, nongovernmental organizations, and communities is essential.

Overcoming Obstacles to Care and Treatment for Women Living with HIV

Deloris Dockrey and Lynde Francis

The lens of HIV is a great revealer of the problems that existed before we got HIV.
—Lynde Francis

After more than 25 years of the global HIV pandemic, the infection rate among women continues to increase. The Joint United Nations Program on HIV/AIDS (UNAIDS) and the World Health Organization report that out of the estimated 33 million people living with HIV, half are women aged 15 years and older. In sub-Saharan Africa, roughly 55% of adults living with HIV are women, and 3 out of 4 (74%) people living with HIV are young people aged 15 to 24 years. In Asia, Eastern Europe, Latin America, and the Caribbean, an increasing proportion of people living with HIV are women and girls.

The increase in the proportion of women living with HIV is primarily due to heterosexual transmission. This trend is especially visible in sub-Saharan Africa and the Caribbean, although women in industrialized countries are increasingly bearing a greater burden of the disease. In the United States, for example, women comprise the fastest growing population of people living with HIV.

The stigmatization of HIV infection makes it difficult for people living with HIV to access care and treatment services. This is often due to their fears of being judged or discriminated against. These fears can be especially acute among women, because they are often more vulnerable to abusive treatment by their spouses, family members, and the greater community. Despite these challenges, women are working to find ways to overcome various forms of stigma and discrimination, just as they have done for generations. It is hoped that through their determined efforts, HIV-positive women can gain greater access to care and treatment services as the scale-up of these services continues. Access to health care for women is a critical component of HIV control and prevention, not only to address women’s health needs and the needs of their families, but also to provide an opportunity to address the serious inequities women have been experiencing since time immemorial.

In many ways, HIV is a “great revealer,” highlighting the many political, socioeconomic, and cultural injustices that disproportionately affect the lives of all women, not just those living with HIV. These injustices include denial of equal rights, gender discrimination, violence, lack of access to education, lack of economic opportunities, and
poverty. As Julie Hamblin writes in the article “The Role of the Law in HIV/AIDS Policy,” “The people who remain most vulnerable [to HIV] are those who are denied the means of protecting themselves against the risks of HIV because of economic need or powerlessness to control the basis upon which their sexual relationships take place.”

In other words, the powerlessness of women fuels the spread of HIV. In order to reverse this trend, the underlying causes of this powerlessness must be addressed. Women living with HIV are a critical voice in the public debate surrounding HIV/AIDS and access to health care. This chapter discusses strategies for empowering women living with HIV to improve their health and well-being alongside personal views of HIV-positive women who have overcome obstacles to accessing care and treatment in resource-limited settings in the United States, the Caribbean, and sub-Saharan Africa.

PEER SUPPORT PROGRAMS: THE WELLNESS COMMUNITY

Programs that focus on women’s well-being and coping skills, such as the Wellness Community for people living with HIV/AIDS at Hyacinth AIDS Foundation (New Jersey, United States), have proven very successful. The Wellness Community at Hyacinth creates an emotionally supportive peer community and provides a setting that actively facilitates interpersonal growth and self-advocacy skills that are predictors of adherence and positive health outcomes. In addition, it fosters an environment in which participants are more willing to assess and address mental health issues. The program is based on the Wellness Community Patient Active concept for people with cancer diagnoses. The Wellness Community helps HIV-positive women take a more active role in their health and health care. They learn how to reduce stress and how to improve the quality of their lives. The program continuously assesses the clients’ progress. Clients are assessed at the start of the program and then again at three and six months. As members of the Wellness Community, women can participate in groups that address stressful issues like loss of control, loss of hope, and unwanted aloneness. Wellness activities build positive relationships, reduce feelings of isolation, and give women a sense of hope. Most importantly, other HIV-positive women in the group provide peer support and make it easier for women to talk about the HIV virus.

Gail, a 55-year-old African American woman, joined the Wellness Community at Hyacinth in 2004. She had been diagnosed in 1989 with AIDS-related syndrome and was told she had less than a year to live. She was so afraid and ashamed of having AIDS that she kept silent about her infection for 12 years. Her silence took its toll in 2001 when she became ill. In desperation, she reached out and was welcomed into a Women’s Wellness group. Within a year of joining the group, she found hope, a sense of community, and the ability to take control over her own health. She remembered the first time she walked into her doctor’s office with a list of questions. She could still see the look of astonishment on his face. He stopped and put down her file, and after 12 years they had their very first conversation about how best to manage her health.

With joy, she said, “It took nearly 13 years to find my voice, but once I did, everything turned around. It wasn’t that my health circumstances had changed, but my ability to manage my life had, and I was a different person than when I first walked through the doors.”

*More information on the Wellness Community at Hyacinth can be found at www.hyacinth.org.*
AM AN HIV-POSITIVE MOTHER, grandmother, public health professional, advocate, and activist in the fight for HIV care and treatment access, and becoming educated on the virus and being involved in the health-care process at every level has helped me to overcome the many obstacles in my life. After working in the HIV arena for more than 10 years, I have come to understand the importance of involvement and advocacy in the lives of people living with HIV.

I remember that my deepest fears, shame, and secrets erupted like lava from a volcano when I was diagnosed with HIV in 1994. Before being diagnosed, I had run away from Jamaica, wanting to make a fresh start in the United States of America. As a young girl in Jamaica, I was sexually abused by a male relative, which I had kept as a secret. When I became pregnant in my teens, I had to live with the disgust and disappointment of my family. I was a single mother with no support from a husband. I thought that emigrating to the United States would erase my past and provide a bright future for myself and my son. But my HIV diagnosis threatened to kill those dreams! For more than 14 years, I have worked to overcome the troubles of my past by educating and empowering myself. I am very active in advocating for my health care and for the public health policies that impact my life and the lives of other HIV-positive women.

But my story is not unique; it is the story of many women. An HIV-positive diagnosis compounds and reveals the problems and challenges in our lives. Over the years, I have experienced the power of telling my story. It has been a significant part of my healing process. Today, I feel stronger and freer than ever before. I believe that what we do to overcome the obstacles in our lives and in our society, and that our choice to forge ahead, is our legacy.

I have found that the support programs that are most successful create an environment where HIV-positive women can freely discuss issues of stigma, sexuality, sexual violence, inequities, and poverty in their lives as they learn about their bodies and the virus.

In 1998, I joined the Sister Connect program offered by the New Jersey Women and AIDS Network.¹ The program is an intensive educational training program designed to provide women with knowledge about HIV/AIDS and related treatments. By the end of the 12-session program, I had learned how to advocate for adequate treatment and appropriate care from health-care providers. We (HIV-positive women) increased our sense of personal empowerment as we learned about our anatomy, our sexuality, the HIV virus, treatment options, and how to read and understand our laboratory reports.

¹More information on the New Jersey Women and AIDS Network Sister Connect program can be found at http://www.njwan.org/sisterrise.html.
OVERCOMING THE OBSTACLES: AN AFRICAN WOMAN’S PERSPECTIVE
By Lynde Francis

I AM A 60-YEAR-OLD, HIV-POSITIVE grandmother, living and working in what could arguably be described as the eye of the storm, sub-Saharan Africa, where UNAIDS estimates that 60% of those infected with HIV are women. Since my HIV diagnosis 21 years ago, I have witnessed a quiet but remorseless revolution taking place. Unlike in Europe and the United States, in Africa, from the onset of the HIV/AIDS epidemic, women have borne the major brunt of its effect. Initially, the women’s movement failed to respond to HIV; the messages surrounding its transmission focused entirely on promiscuity and other immoral behavior, with which women’s movements did not immediately identify. Within this context, marriage was being promoted as a form of protection.

The process of public realization closely mimicked the personal process from HIV diagnosis to acceptance: first, denial and disbelief; then, fear and panic (the “blame game”); after that, depression, hopelessness, and isolation. Ultimately, with increasing information, acceptance brought with it the final stage: “What next?” and “What can we do to fight back?”

Even in the late 1980s, there was already a vanguard of brave and farsighted “women warriors”—women like Auxillia Chimusoro, the first woman to publicly declare her status in Zimbabwe; Winnie Chikafumbwa in Malawi; and Bridgette Syamalevwe in Zambia—unsung heroines for the most part. They sounded a call to action and put their own lives on the line to alert others to the danger confronting them.

In the face of stigma and ignorance, they founded support groups and networks of people living with HIV/AIDS. Against all odds, they reached across borders and came together in what was to become the International Community of Women Living with HIV/AIDS to demand access to rights and treatment, rights that would not be realized in their own lifetimes. One of the most striking aspects of the emerging movement of people living with HIV/AIDS, from the beginning, was its exclusivity. It seemed that the stigma and isolation inflicted on those living with HIV superseded other socioeconomic, race, and class barriers. HIV-positive women from all walks of life found they had more in common than they had differences; and a “positive community,” almost a “POZ family,” became the fertile ground from which change would grow.

At a conference in Mozambique in 1992, I presented a paper entitled “Sexuality after Seropositivity.” This was an inconceivable concept at that time; HIV infection meant the end of any normal emotional, romantic, or sexual existence. It was then that I gave HIV my own personal name, “The Great Revealer,” as I was besieged afterward by people who had never thought beyond the health/medical paradigm. They wanted to know how I could find anything positive about seropositivity. It seems self-evident now, but back then, we had not yet fully grasped the implications of HIV as a vehicle for change.
Women are using the Wellness Community to empower and improve their lives, and some are returning to work. Many women have become active in public policy advocacy and campaigning groups, calling on their legislators to address public health policies that affect them. HIV-positive women are encouraged to tell their stories, to give voice to their struggles, and to use their stories as weapons for change.

ADDRESSING VIOLENCE AGAINST WOMEN

In some households, domestic violence is an obstacle, and nonconsensual sex is pervasive in the lives of many women and girls. Marta Dillon, in her article “In Front of the Mirror,” writes of a woman named Janaina from Pernambuco in Brazil who was barely 30 but had a long and bleak story that was difficult to tell. Janaina lives with her two children at a shelter for female victims of violence. When she was 9, she was given to a family to work as a maid. At 13, that family sold her into a prostitution ring. Janaina never went to school but taught herself to read. When she finally got away from prostitution, she found out that she was HIV-positive. Her story illustrates the strong link between violence against women and HIV.

The international campaign Women Won’t Wait is a coalition of organizations and networks committed and working to promote women’s health and human rights in the struggle to comprehensively address HIV and end all forms of violence against women and girls. The campaign focuses on gender-based violence against women and girls. Among its many activities, the campaign collects stories of women, like Janaina, who have experienced violence and abuse in their lives. These women speak of how they overcame their struggle and how they have improved their lives and the lives of their families.

NETWORKS FOR THE EMPOWERMENT OF WOMEN LIVING WITH HIV

HIV-positive women who are educated about the progression of the disease and who are allowed a safe environment to share their experiences emerge stronger and more determined to take control of their lives. Networks of people living with HIV/AIDS create safe spaces for women to become educated and involved in the issues that affect them. Once a woman begins to advocate for her needs, she begins to share her knowledge with others. The strongest supports for women are other women who can share their experiences. The principle of greater involvement of people living with HIV (GIPA) is embraced by many HIV-positive networks. GIPA aims to realize the rights and responsibilities of people living with HIV, including their right to self-determination and participation in the decision-making processes that affect their lives.

The Global Network of People Living with HIV/AIDS (GNP+) spearheads the GIPA principles. Representing people living with HIV, GNP+ is a global network that works on equal footing with all of its six affiliated regional networks in Africa, Asia, the Caribbean, Europe, Latin America, and North America. The role of GNP+ is to provide a platform for the diverse voices of people living with HIV globally, to present evidence in the global arena, and to support capacity building of individuals at the regional, national, and local levels. The core business of GNP+ is advocacy. GNP+ programs and platforms are based on the following broad key objectives:

*More information on the Global Network of People Living with HIV/AIDS can be found at www.gnpplus.net.
• Increased access to treatment, care, and prevention programs for all people living with HIV
• Decreased stigma and discrimination directed toward people living with HIV
• Increased and more meaningful involvement of people living with HIV at all levels and in every aspect of the HIV response, including service implementation and decision making

As women and girls become empowered and educated, they can clamor for the right to become involved in the scale-up of care and treatment programs. With the support of networks for people living with HIV, women can continue to advocate for changes in how society addresses the disparities and inequities that women experience. Women must become active and demand that decision makers be held accountable for the promises on women’s rights that they have endorsed. Government leaders must be made accountable for providing greater access to treatment and care for women, their children, and their families.

EXPLORING LINKAGES AND MOBILIZING COMMUNITIES

Today, HIV is considered a cross-cutting topic in all areas of discussion and all aspects of development. The mainstreaming of HIV has become the golden key to unlock donor doors. But most of all, it has enabled dialogue around areas previously considered taboo. Domestic violence, gender inequity, rape, and incest are now out in the open. Sexual and reproductive health and rights are no longer discussions held only behind closed doors but are part of the strategy to eliminate HIV.

For the first time, we are grappling with the inextricable linkages between economic and social development, health, environment, gender equity, and long-term survival of the whole human race. What could not be spoken is now exposed to the relentless spotlight of our vulnerability to HIV. This vulnerability will persist unless we come together and address the challenges we face in a united effort.

A major part of this change is the realization that our greatest weapon in this enterprise is the education and empowerment of women and girls. This can only be done through realistic, practical, and down-to-earth skills-training that enables women and girls to improve their own livelihood and that of their communities. An important aspect of this empowerment is to inform women and girls of the rights they possess, thus helping them to realize that culture and tradition are not immutable and that they do possess the power to change it.

An example of this concept in action is offered by the program run by The Centre (Zimbabwe) and funded by The River Fund to train 30 HIV-positive rural women from 10 provinces in western Uganda. Prior to the training, none of them had secondary education, and the sole criterion for attendance was a basic understanding of English and literacy in the vernacular. Most of the original group consisted of widows or divorcées with children, aged 25 to 60. The initial training in 2005 was on long-term survival skills for living positively with HIV and took place at a mission school in Tororo. The women were taught basic HIV information, nutrition, disclosure, self-care, stress management, infant and child feeding, and basic home-based care skills, among other topics. At the end of the one-week training, they went home with instructions to put these skills into practice in their personal and community lives.

One year later, in 2006, the same group returned to Tororo with only one dropout. They shared how the training had changed their lives and their position in their community, their successes, and their failures. Through a SWOT (strengths, weaknesses, opportunities, and threats) analysis, they looked at how they could improve on areas where they felt they had failed. Without exception, all of these women had gone further than their own
immediate family circles and had initiated skills-sharing sessions with other women in their communities. They had also approached gatekeepers and stakeholders, and many of them were now sitting on clinic community boards, working with community-based organizations, or collaborating with others to provide home-based care to neighbors and friends.

They then underwent a second training that taught the women how to assess local resources and how to perform a needs analysis. They learned to plan and mobilize resources and to open gates once kept closed by community leaders. They learned how to assess the needs and expectations of the target community and compile a program agenda. Participatory training techniques were taught, as well as how to build indicators for monitoring and evaluation into their programs. The last three days of this one-week training were completely managed by the women themselves as a “learning by doing” exercise. All participants contributed to planning the program, presenting the sessions, conducting focus-group discussions, and giving feedback to the plenary group.

In September 2007, each provincial group involved in the original training nominated one representative to attend the third session, training of trainers (TOT), phase III. Each representative in this TOT group brought with them two women they had done baseline training with in their community during the previous year. Twelve representatives of the original cohort, together with 24 new participants, attended this session. After an initial team-building exercise, the TOT group was given a day to design the program for the second-stage (phase II) training of the new group over a two-day period, while a one-day baseline debriefing workshop was conducted to ascertain the level of knowledge achieved by the new participants.

Our new participants completed an evaluation of each session run by the TOT group and scored them on content, style, communication, participation, and fun (something they would never have thought themselves capable of a week before!). The feedback reports from the provinces showed that the women from the original cohort had held direct training or interactive sessions with over 5,000 people in the previous year! This was confirmed by the new group of 24 participants, who had been involved in the baseline training the previous year and told of the workshops held in church halls, schools, fields, and even at football matches.

By October of the same year, the 12 representatives, now TOT graduates, were holding phase I trainings in four other provinces, thus completing the ownership and continuation of the program by and for the community. The monsignor and bishop of the mission where this program has evolved was proud to hand out certificates to the women and confirmed that, at the outset, he had not expected such a complete transformation of the women involved “from mice to roaring lions”!

CONCLUSION

Nelson Mandela, former president of South Africa, stated, “For every woman and girl violently attacked, we reduce our humanity. For every woman forced into unprotected sex because men demand this, we destroy dignity and pride . . . For every moment we remain silent, we conspire against our women. For every woman infected by HIV, we destroy a generation.” As women work to educate, train, and empower themselves, they are also demanding that their government, their men, and the larger community change some of the norms and traditions of the past. As a society, we must change current socioeconomic and political conditions and build opportunities for women as well as men to address the issues of stigma, gender inequity, and disparities that negatively impact how women access HIV care and treatment.
TRANSFORMING MALE GENDER NORMS TO ADDRESS THE ROOT CAUSES OF HIV AND AIDS
Andrew Levack
EngenderHealth, United States

It is widely recognized that gender norms—societal expectations of men’s and women’s roles and behaviors—fuel the global HIV epidemic. Women’s low status in many societies contributes to limiting the social, educational, and economic opportunities that could help protect them from infection. Traditional gender norms also give women the message that they need to be submissive or to let men take the lead in relationships, which further contributes to putting them at risk for HIV. At the same time, traditional male gender norms encourage men to equate a range of risky behaviors—the use of violence, substance abuse, the pursuit of multiple sexual partners, the domination of women—with being manly. Rigid constructs of masculinity also lead men to view health-seeking behaviors as a sign of weakness. These gender dynamics all play a critical role in increasing both men’s and women’s vulnerability to HIV.

A Model for Working with Men
Over the past decade, a growing number of innovative HIV-prevention programs around the world have worked with men to challenge traditional gender norms and develop alternative, healthier gender norms. They are unique in allowing men to participate in a reflective process that explores how gender inequities and rigid messages about masculinity contribute to HIV, sexually transmitted infections, gender-based violence, and other health-related problems. These programs allow men to understand how traditional masculinities can lead to unhealthy behaviors that put both them and their partners at risk. These “transformative” programs ask and encourage men to challenge harmful gender norms and embrace alternative models of masculinity that support their own health. This can lead to improved communication with partners, increased condom use, reduction of sexual partners, delayed initiation of sex, increased utilization of HIV services, increased support of their partner’s use of services, and an increased role in the care and support of people living with HIV/AIDS.

Transformative approaches share a set of operating principles. First, they view men in a positive light. Rather than portraying men as vectors of disease, these programs recognize that many are already playing a constructive role in the lives of their families and supporting the rights of women. They also acknowledge that masculinity can be defined and expressed in a variety of ways. Using the term “masculinities” suggests that gender norms are diverse, complex, and dynamic. Transformative programs explore how masculinities are deeply intertwined with culture, race, class, age, socioeconomic status, and sexuality. Additionally, they recognize that men have a personal investment in challenging current norms and can be allies in improving their own and their family’s health. Finally, all transformative programs recognize the need
to work with women’s groups to ensure partnership with and accountability to women. In the end, the goal of this work is to develop respectful, trusting, and egalitarian relations between men and women that will attack the deep roots of HIV infection and enhance the lives of both sexes.

Implementing Transformative Approaches
Transformative programs for men exist in many countries, with most initiated by local and international nongovernmental organizations (NGOs). However, as this work expands, local and national governments are joining the process in settings such as schools, prisons, police wards, and military bases.

Most transformative programs offer some type of intensive group process that encourages a very personal reflection on gender values, examining the costs to both sexes of negative gender dynamics. The workshops also provide an opportunity to explore progressive views of gender relations in a safe and supportive environment. Following the initial activities, participants are given information on a range of health issues, including HIV, and engage in exercises that constantly refer back to the issue of gender. For example, an activity about HIV transmission would explore the societal messages men receive that put them at higher risk for HIV.

Transformational educational processes can work with men alone or bring men and women together. One of the best examples of the latter is Stepping Stones, a participatory gender-focused process that brings together men and women from a community to engage in a discussion and analysis of factors in their environment that make them vulnerable to HIV. This training methodology was designed in 1995 in Uganda and has since been adapted and modified to suit the needs of populations in varied settings throughout the world. Stepping Stones uses a series of 18 workshops with four groups of older men, older women, younger men, and younger women. At the end, the groups come together, and the entire community entertains “requests for change” as the groups perform dramas reflecting the lessons learned. A great strength of the Stepping Stones approach is that it works directly with a diverse group of community members to challenge harmful social norms within that environment.

An Ecological Model
Workshops with small groups of individuals in a community can be very powerful but can also be limited in creating large-scale social change. Once a workshop ends, participants return to a patriarchal society where change is not supported. To address this, many transformative programs with men have adopted an ecological model that addresses multifaceted aspects of an environment to effect personal and social change. This includes implementing small workshops; mobilizing communities; supporting local institutions such as schools, NGOs, and religious bodies to implement this work; working with media partners to conduct large-scale campaigns; and supporting government structures to develop supportive policies and legislation.

There are many excellent examples of this holistic ecological model. In South Africa, for example, EngenderHealth’s Men As Partners program establishes community action teams made up of workshop participants to promote
and sustain change in their personal lives and in their communities. The teams work closely with trained staff from NGOs to support events such as health fairs, community theater productions, and mural paintings with gender-related themes. Working together, team members reinforce a new social norm in which men take an active stand for HIV/AIDS prevention and the elimination of gender-based violence, also introducing this norm in the environments where they live.

Other NGOs have adopted a variety of creative ecological efforts. In Brazil, Instituto Promundo’s Project H implemented a lifestyle social marketing campaign that disseminated messages about gender equality through advertisements, peer promoters, and magazine articles. The campaign also associated gender equality with a specifically designed brand of condom.

Another example comes from India, where a coalition of local NGOs and gender activists established a statewide campaign called Men’s Action for Stopping Violence against Women, creating a social movement of men taking an active stand against gender-based violence. The campaign involves marches, rallies, and large community events that reach thousands of men.

Larger media efforts are also starting to take hold. In South Africa, a consortium of NGOs working on men’s issues has convinced the South African Broadcasting Corporation to devote news coverage and public service announcements to gender issues. Meanwhile, MenEngage—an international alliance of organizations working on gender issues—is recruiting national and international male celebrities to serve as gender equality ambassadors who will be mobilized to reinforce progressive gender social norms.

Challenges for the Future

The emerging movement of work with men and boys brings optimism and also challenges. As the field grows, programs are being challenged to scale up their interventions to reach larger numbers of men while also accounting for the complex nuances involved in adapting to different regions, countries, and communities. Programs cannot be generically replicated in new settings, and communities are initially likely to resist the idea of challenging existing gender norms. To address this, programs must identify gender activists and professionals from within communities to champion this work and navigate it in an appropriate manner. As these leaders initiate new male programming, they should always retain the shared operating principles of this important work: to always serve the shared interests of women and men, and to view men as a positive resource in creating a healthier, more gender-equitable world.
REFERENCE LIST

In ‘Remembrance

Sadly, Lynde Francis passed away on March 31, 2009 at the age of 62. Lynde will be remembered and respected around the world for her devotion to advocacy and education on all aspects of holistic management of HIV, as well as for her role as an advocate for the meaningful involvement of people living with HIV. She was a true pioneer who embraced life to the fullest and whose spirit will continue to inspire us all for generations to come.
Adopting Human Rights Standards in the Scale-Up of HIV/AIDS Care: Lessons Learned from Argentina, Botswana, and Thailand

c Thai AIDS Treatment Action Group, Thailand  
d The Foundation for Studies and Research on Women, Argentina

This chapter sets out three narrative summaries from resource-limited settings in three continents, across the global south. From Argentina in South America, to Botswana in sub-Saharan Africa, and across to Thailand in Southeast Asia, activists in the field strive for the adoption of human rights standards in the scale-up of HIV/AIDS care, premised on the most fundamental tenet of human rights: the dignity inherent in every human being. Human rights standards are best realized in a legally and socially enabling environment that upholds justice and respects equality. The arguments of proponents of a rights-based approach derive added strength in contexts where stigma still tends to be a central challenge to HIV/AIDS, in an era when, in principle at least, the primacy of human rights in the care and prevention of the epidemic is accepted. The challenges in this sphere are aggravated by increasing poverty, consumerism, and socioeconomic inequity in the age of globalization. Gender inequality, lack of sexual education, and the feminization of poverty and HIV/AIDS are more common in countries that are developing and/or in transition. These countries are also where certain members of society are particularly vulnerable, especially women, young people, people living with HIV/AIDS, and injecting drug users (IDUs).

ARGENTINA

Latin America and the Caribbean constitute a region with an enormous wealth disparity. In Argentina, recent economic decline has further widened the wealth gap and left an increasing number of impoverished people. This increase in poverty combined with the stimulation of consumerism by publicity geared toward adolescent boys and girls promoting eroticism, and poor access to sexual education, family planning services, and condoms as a result of religious influence, specifically the Roman Catholic Church, facilitate an increase of adolescent pregnancies and HIV infection. Studies have shown that...
adolescent pregnancy in Argentina increased specifically within the 10–14-year-old age group. Since 2004 the Argentine Ministry of Health reported that new HIV infections among young people 15–24 years old predominate in women over men. This increase of infection rates was also accompanied by an increase in poverty mainly affecting women and girls. According to the 2001 census, 70% of all young people in Argentina live in situations of poverty, and so do 43.6% of all women living in Argentina’s urban centers. This feminization of poverty has translated into the feminization of HIV/AIDS.

Since its creation, the Foundation for Studies and Research on Women (FEIM) has focused its approach on the right to information of adolescents and young people based on the Convention on the Rights of the Child (CRC) and the Convention on the Elimination of All Forms of Discrimination Against Women (CEDAW). FEIM works to promote access to information about sexuality and HIV/AIDS from a gender perspective through peer education. FEIM recognized the lack of understanding and knowledge on these issues among youth at a national awards event in 1994 when young people were asked to express their opinions and concerns about adolescent pregnancy. Many had romantic and conservative views on teen pregnancy and didn’t perceive the risk of HIV/AIDS because it is only associated with men who have sex with men, sex workers, and drug users. They were also unaware of their right to information and health care due to their ignorance of the CRC, and their right to health afforded by the constitution. They didn’t recognize sexual inequalities, women’s rights, or the impact of stereotyped gender roles. FEIM decided to train peer educators to reach out to young people who could become advocates themselves on issues of sexuality and HIV from a gender perspective based on human rights. This peer-based approach has been notably successful in Argentina. The United Nations Development Fund for Women (UNIFEM) and United Nations Children’s Fund (UNICEF) invited FEIM in 2000 to publish their experience in “Sexuality and Health in Adolescence: Theoretical and Practical Tools to Exercise Our Rights.”

It was out of this success that FEIM received funding to create a national network of young people to promote sexuality and HIV/AIDS prevention. This network, RedNAC (National Network of Adolescents and Youth for Sexual and Reproductive Health), has served as a structure for the multiplication of sexuality and HIV/AIDS awareness as well as advocacy training on these rights. Since its inception in 1999, RedNAC has been a point of reference for more than 5,000 young peer educators throughout the country.

FEIM and RedNAC took on the responsibility of raising awareness among secondary school students that otherwise have no formal access to sex education. The workshops highlight issues relating to sexuality and HIV from a gender perspective and raise awareness on the principles of the CRC, particularly the right to access education, information, and health care, as well as those of CEDAW. The workshops also encourage young people to access health-care services so that they may protect themselves from HIV infection and unwanted pregnancy. FEIM and RedNAC continue to successfully build the capacity of youth to secure their right to information on sexuality and HIV/AIDS in a Catholic and conservative country like Argentina. Challenges have included overcoming school authorities’ fears of being reported for allowing people to talk about sexuality and opposition from a number of professors. However, there has been support from the majority of parents and students, who have asked for and even demanded the workshops in their schools.
The Botswana Network on Ethics, Law, and HIV/AIDS (BONELA) was established in 2001 with the aim of facilitating the use of a human rights approach to the national response to HIV/AIDS. Initially a small organization with very limited resources, BONELA recognized early on that the main challenge of using a human rights approach to HIV in Botswana was the lack of understanding on the part of different stakeholders regarding the meaning and applicability of human rights in their own cultural, political, and social contexts. This lack of understanding was prevalent not only among community members engaged in diverse activities such as the provision of home-based care, testing and counseling, HIV treatment, and support of people living with HIV, but also among strategic decision makers such as heads of government agencies and parliamentarians.

Many national governments, including the government of Botswana, are committed to human rights as a convincing approach to HIV. The “Declaration of Commitment on HIV/AIDS,” which resulted from the United Nations General Assembly Special Session on HIV/AIDS (UNGASS) in 2001, is widely supported by governments from around the globe and is an outstanding example of the international commitment to use a human rights–based approach to HIV. The declaration emphasizes the need for a realization of human rights and fundamental freedoms for all in order to reduce vulnerability to HIV/AIDS and further declares that the “respect for the rights of people living with HIV/AIDS drives an effective response.” Many national governments initially agreed in principle to the declaration, but it was not immediately clear how they would translate these principles into their national programs. A further difficulty in Botswana was the general lack of understanding of human rights concepts in all sections of society. In this environment, BONELA set to work. The first step was to sensitize as many community members as possible at all different levels of society on the link between human rights and HIV and in ways of adopting a human rights approach. It soon became evident that there was a need for contextualized and innovative training materials that could be utilized in different communities. In 2004 and 2005, BONELA engaged in an extensive project that involved researching, writing, and pilot testing its own training materials, resulting in the publication of Human Rights and HIV: A Manual for Action, a 14-module training program, partly bilingual (English and Setswana, the two national languages in Botswana). The aim of the manual is to increase awareness among all stakeholders on how to apply human rights concepts in their practice, in order to ensure nondiscrimination toward people living with HIV/AIDS. It also demonstrates how those who have experienced discrimination due to their real or perceived HIV status can be assisted. The manual covers a diversity of topics, such as HIV and the law, the right to health, confidentiality, sexuality, and human rights, and makes a concerted effort to discuss culturally sensitive topics such as the inclusion of sexual minorities in HIV care and prevention.

The questions posed most often when discussing human rights concepts in Botswana center around two themes: First, are human rights concepts applicable in Botswana, or are they imported Western concepts that are being imposed by international agencies and foreign governments? Second, is there a need to discuss human rights protections with regard to people living with HIV in a country that has undeniably set a new standard on the African continent by providing free antiretroviral medication? BONELA continues to answer both questions through their public education and advocacy. A starting point to contextualize human rights in Botswanan society is to explain them in relation to the local concept of *botho*, which can be roughly translated in English as “humanness.” It is
request BONELA to assist with training and education. The increased engagement with communities further highlighted the need for a greater understanding of provisions in Botswana law to counteract discrimination of all forms. In early 2005, BONELA started legal literacy workshops specifically aimed at people living with HIV and service providers to enable them to understand existing legislation with regard to discrimination and HIV. Of particular importance in this area is the understanding of labor laws. These workshops are facilitated by the BONELA legal officer, a lawyer by training, who also facilitates legal aid clinics during those workshops in all the geographic areas of Botswana.

However, the increased awareness of stakeholders with regard to the law has also brought to light the many human rights challenges experienced by people living with HIV. Although BONELA initially offered only very limited legal services, the organization now runs a full legal aid clinic that represents people who have experienced discrimination based on their real or perceived HIV status. Botswana does not provide legal assistance to those who are poor or disadvantaged, and the BONELA legal clinic addresses an obvious gap in this regard. It is disappointing to see the increasing number of clients who are seeking help from the clinic, indicating the dire need for more stringent laws to protect people from HIV-related discrimination, in particular at the workplace. Law reform is only one strategy to protect people from possible discrimination, and such reforms will need to be accompanied by public education about the laws and the monitoring and enforcement of such laws. In an attempt to make legal advice available to an even greater number of people, BONELA also has run a regular call-in show on national radio since mid-2007.

In the past three years, BONELA has made the training of health workers and people infected with HIV a priority in all education activities. Training is based on the understanding that the provision of
high-quality care needs to be carried out within an environment that protects and promotes human rights. As noted above, Botswana provides antiretroviral therapy (ART) in its public health facilities. However, it has become increasingly clear that many patients are not well informed about the medication they are taking. Ignorance about antiretrovirals (ARVs), biomedical issues with regard to HIV infection, and appropriate therapy for HIV and opportunistic infections often makes it difficult for patients to make informed choices about their health. With this in mind, BONELA created a coalition of civil society groups on treatment literacy, which resulted in a Treatment Literacy Program managed by BONELA. The program utilizes community treatment literacy trainers who, in turn, educate communities on treatment literacy issues. Repackaging scientific medical information to be easily communicated among community members is a first step in empowering communities to take charge of their own health and making them active participants in their health care. Ideally, this program will result in many informed and active community members who will monitor government services and vigorously contribute to the provision of adequate and high-quality care services to people infected with HIV in Botswana.

BONELA has been successful in training communities at the grassroots and institutional levels. However, it has been difficult to communicate a human rights approach successfully to policymakers, decision makers, and parliamentarians. People at these levels may be present at international gatherings during which human rights standards are agreed upon, but they are difficult to reach in terms of in-depth training on the practical application of a human rights approach. It is imperative that organizations, such as BONELA, enter into creative partnerships with institutions within government to initiate innovative, interesting, and targeted trainings on HIV and human rights that will be accepted by policymakers and opinion leaders.

THAILAND

The government likes to say there are no more injecting drug users. Well, they are sort of right. Thanks to them, we’re all in prison, or in heaven. —Paisan Suwannawong

On International Human Rights Day (December 10), 2002, 50 drug users (primarily IDUs, many HIV-positive) organized in Bangkok to found the country’s first network of people who use drugs. “If we don’t do it, nobody will,” said one HIV-positive former user. “How much longer can we watch our friends die of AIDS, in prison, untreated, with no dignity?” Its seminal project was a peer-to-peer human rights documentation project among IDUs that examined barriers to accessing health-care services and abuses by law enforcement officials and within the criminal justice system. That historic meeting in December was a report-back on the findings and on how to move advocacy forward, ultimately leading to the birth of the Thai Drug Users’ Network (TDN).

The network committed itself to “promote the basic human rights of people who use drugs, in order to be able to live equally and with dignity in society.” For nearly 20 years, the government had ignored a staggering HIV epidemic among people who inject drugs and, despite a 50% prevalence rate, eschewed evidence-based approaches including methadone maintenance and distribution of clean injecting equipment for a “just say no” approach to drugs that relied on law enforcement rather than public health principles and strategies. Later, as antiretroviral therapy became increasingly available through the government’s generic production and national health insurance schemes, the lack of access by people who use drugs was another acute injustice.

From TDN’s perspective, the time was right for drug-user activism to bring attention to the critical human rights situation: within two months of TDN’s founding, the government announced a
“war on drugs” of unprecedented severity; and within the crackdown’s first three months, more than 2,000 people were extrajudicially executed. Tens of thousands more were arbitrarily arrested and detained and forced into military-run boot camps to clear their names from blacklists. Yet the public, including AIDS and human rights nongovernmental organizations (NGOs), was largely silent. The climate of fear induced by the repressive nature of the campaign and strong-arm measures used to implement it was overwhelming but did not hamper TDN’s activism. “What do we have to lose?” said one cofounder. “How can I live with myself as thousands die and with no one speaking out about the injustices that are being committed? How will I feel later, looking back on this time, if I stay silent?”

TDN’s first demonstration was a march on the Government House, where they held a mock funeral for those who had died of AIDS or were killed in the drug war, and demanded the prime minister stop the drug war and investigate the killings. Protestors carried signs proclaiming, “Thai government drug policy = Drop Dead!” and “Protect the rights of people who use drugs.” Body bags and funeral wreaths were set up in front of the gates of the prime minister’s offices.

Over the next months and years, TDN used numerous strategies to bring national and international attention to the health and human rights crises facing people who use drugs in Thailand. As the drug crackdown worsened, the prime minister and other government officials made regular pronouncements in the media that people involved with drugs were “enemies of the state” and a “threat to national security” warranting harsh punishment and imploring local citizens to get involved in surveillance and reporting. TDN approached numerous government bodies including the parliament and the National Human Rights Commission, and even implored the king to intervene and stop the abuse and killing.

TDN contacted allies across the globe to help organize an “International Day of Solidarity against the Thai War on Drugs,” where activists in at least a dozen countries from South Africa to Nepal brought the network’s demands to their Thai embassies and spoke out against the human rights violations on Thai drug users to the media, attracting global attention. TDN raised the visibility of the government’s failure to respect and protect the rights of people who use drugs at two major international conferences held in Thailand, the International Conference on the Reduction of Drug-Related Harm (2003) and the International AIDS Conference (2004), belying Thailand’s claims of success in responding to HIV/AIDS and promoting “access for all.”

Human Rights Watch conducted a special investigation into HIV, drug use, and the war on drugs at TDN’s request, and UN Special Rapporteurs were at the same time condemning Thailand’s lack of attention to the negative impact of its approach and requesting urgent investigation into the drug war killings. TDN’s harm reduction proposal for US$1.3 million was granted by the Global Fund in 2003, the first award of its kind to a community group and one which had bypassed its country-coordinating mechanism due to the political sensitivity of the issue.

TDN has made efforts to promote the involvement of people who use drugs in national policymaking and programming and to spearhead peer-driven services and advocacy campaigns to demand that the government fulfills its human rights obligations, in particular the rights to life and health for people who use drugs. Despite these efforts, the criminalizing and stigmatizing environment continued to push people who use drugs to the margins and undermine their efforts at every turn. Despite amendments to the drug laws that reclassify certain drug users as “patients,
not criminals,” police continue to interfere with access to methadone and other services. Despite the abolition of nonmedical exclusion criteria for ART access due to TDN’s own advocacy, people who use drugs (and even methadone patients) are routinely denied access at the hospital level. Extreme ignorance and discrimination by health-care providers and others in society and deeply entrenched political aversion to legally recognizing people who use drugs as people with dignity and rights conspire to push drug users further underground and away from essential information, services, and support.

People who use drugs continue to be subjected to compulsory drug treatment of no proven efficacy, mandatory testing without counseling, substandard or denial of HIV treatment, lack of access to information, unequal treatment before the law, and numerous other injustices. UN agencies working in Thailand, particularly the Joint United Nations Program on HIV/AIDS and United Nations Office on Drugs and Crime, have not responded positively to TDN’s requests for assessments of the impact of the drug war and criminal justice approach on drug users’ enjoyment of basic human rights.

TDN and other drug user advocates recognize that people who use drugs should and must be at the center of the response to the health and rights situation of their community; however, without a conducive legal and social environment to promote and support their empowerment and access to information and skills, as well as active participation in planning and programming, people who use drugs will continue to be subject to increased vulnerability to HIV, hepatitis, overdose, incarceration, and further risks without equal access to remedies and equal treatment before the law. History will continue to repeat itself until the government and other complicit actors are held accountable.

**REFLECTIONS AND RECOMMENDATIONS**

The following reflections distill recommendations from some of the more successful efforts in this area, while documenting important lessons learned from less successful efforts:

- Although human rights should be a core element in the global struggle against HIV/AIDS, they often constitute the missing link, especially in practice. Making the transition from theory to practice is a key challenge in adopting human rights standards in the scale-up of HIV/AIDS care, support, prevention, and treatment. Efforts should focus on program implementation that treats human rights as an inherent part of the comprehensive care framework. This will help move us forward in both the human rights and HIV/AIDS arenas.

- A range of proactive strategies can be successfully adopted in promoting rights-based approaches, including (where appropriate) peer-based approaches and gender perspectives. Actions taken should include training for sensitization, awareness raising, and education and capacity building and should target peer educators, focal people, community activists and members including people living with HIV/AIDS, health-care providers at different levels (grassroots and within institutions, e.g., government, private, NGO), and communities at large. The creation of a group of key stakeholders for the application of human rights standards to the national response to HIV is important. Methodologies used can include workshops, legal and treatment literacy programs, advocacy, legal aid, comprehensive training materials, peer-to-peer human rights documentation projects, and legal and policy review aimed at reform. Strategies may sometimes be more extreme and/or reactive, when necessitated by the immediacy of the situation.
• Policy and programming need to be evidence based and take account of public health principles and human rights. People surviving at the margins of society tend to get excluded, stigmatized, and criminalized by unequivocal adherence to law enforcement and the criminal justice system, which predate the realities of HIV/AIDS. Human rights standards mandating elimination of discrimination through ignorance and prejudice would complement rather than contradict public health objectives.

• Contextualization/assimilation of concepts related to human rights that are ingrained in local cultures makes the ostensibly “Western” ideology of human rights more acceptable to non-Western societies. At times, these indigenous human rights principles can be used to help discuss issues when political, cultural, and religious beliefs pose barriers to the equitable scale-up of prevention and care services.

• Policymakers and administrators at the highest levels have often been the least receptive to human rights concerns, leading to suggestions of targeted training and innovative approaches. There appears to be a lack of understanding between activists and political leadership, manifested at different levels, ranging from apathy and indifference to outright abuse. This is both unfortunate and ironic, given that human rights as well as related responsibilities are an embodiment of the very obligations undertaken by governments in international relations, policy, and law. Here it is important to recognize the space between entrenched political power and social activism, which provides ground for constructive engagement by all parties and a role for academics, jurists, judges, and other independent stakeholders in the quest for responses that seek to reconcile conflicting interests. Where national governments have been uncompromising, international institutions, the media, and pressure at global, regional, and national levels have been helpful in promoting the human rights dimension.

• Scientists and state officials at key decision-making levels need to be more open to human rights and social realities. Given the cross-cutting nature of HIV/AIDS, responses require all parties, including activists, to transcend the comfort of their own fields to understand the unknown. Traditionally belonging to the disciplines of public health, medicine, and the natural sciences, the all-embracing nature of the epidemic leads to its consideration in the social sciences including law, policy, economics, and sociology. In relation to research methodologies to ground policy, most research in relation to HIV/AIDS still involves only or mostly quantitative study. HIV/AIDS and responses to it, however, involve a range of social and human factors. These are less measurable and amenable to quantitative study, and essentially require qualitative study.

• Human rights and HIV/AIDS discourse would benefit from the overall understanding that this linkage is not unique, isolated, or revolutionary. The link is natural, logical, and established in theory. Beyond HIV/AIDS, it is part of a slow evolution, involving a broader paradigm shift in policy at the national, regional, and global levels that includes good governance; human security (and not merely state and national security); and human, social, and sustainable development including rights-based approaches to development. Key values common to each of these approaches include protection, inclusion, and nondiscrimination; access to information and to support and services (especially health care and education); justice and legal redress; participation and empowerment; and transparency and accountability. All these approaches tend to be people centered, and people affected by related policies, planning, and programs need to play a decisive role.
• When many varied interests lie in one-and-the-same terrain, conflicts arise. For instance, the interests of human rights may sometimes appear to run counter to the interests of public health. Contradictions, whether apparent or real, can be eliminated through appreciating the complexities that arise in a multidisciplinary field; by balancing conflicting interests, for example through laws, policies, and programs that involve multisectoral responses; and most of all, through understanding the cyclical relationship between HIV/AIDS and human rights: when stigma and discrimination are a primary challenge, responses need to address this reality; just as people with HIV/AIDS experience abuse of rights, vulnerability to HIV/AIDS thrives on violations of rights. To break this vicious circle, we need to integrate human rights standards in the scale-up of HIV/AIDS care as well as prevention.
REFERENCE LIST

HIV Care, Treatment, and Prevention in Conflict Settings

Susan Purdin, Wendy Venter, and Roxanne Saucier

International Rescue Committee, United States

IN THIS CHAPTER WE DESCRIBE ISSUES that the International Rescue Committee (IRC) has encountered when addressing HIV in war zones—settings where human rights violations are rampant and providing HIV programming is fraught with challenges. First we discuss the characteristics of humanitarian crises. We then cover the variables of the HIV epidemic in these settings. Next we explore the unique challenges and opportunities of providing assistance in these settings. Finally, we provide case studies and lessons learned illustrating IRC’s experiences in selected field sites and a framework used to guide such interventions.

CHARACTERISTICS OF HUMANITARIAN CRISSES

A humanitarian crisis is defined as a situation that “threatens the lives and well-being of large numbers of people and requires extraordinary action to ensure their survival, protection, and adaptation.” Humanitarian crises may result from natural disasters or armed conflicts; in this chapter we focus on humanitarian crises in the context of armed conflicts as these are the settings where IRC operates. Founded in 1933, the IRC is a global leader in emergency relief, rehabilitation, protection of human rights, postconflict development, resettlement services, and advocacy for people uprooted or affected by conflict and oppression.

In the past 50 years, violent conflicts have taken the lives of millions of civilians and displaced tens of millions more. Current global estimates show that more than 38 million people are living as forced migrants, having fled their homes as the result of conflict. There are an estimated 13.9 million refugees (people who “owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion are outside their country of nationality”). An additional 24 million people have fled conflict seeking safety but have not crossed an international border; they are called internally displaced persons (IDPs). The vast majority of conflict-related displaced people reside in resource-limited settings—either within the country experiencing conflict or the country hosting refugees.

Conflict and HIV intersect dramatically in sub-Saharan Africa. The region not only is the most affected by the AIDS pandemic but also is profoundly affected by the movement of people fleeing conflict and persecution. The 22.5 million people living with HIV in sub-Saharan Africa constitute...
nearly 90% of the children and 68% of the adults infected with HIV worldwide. In this region, where 21 countries are experiencing ongoing political conflicts, 76% of the world’s AIDS-related deaths (1.6 million) occurred in 2007.7-9 A humanitarian crisis is usually seen as a sudden event that threatens life and results in large population movement. An example of this type of crisis is the flight of Rwandans to the Democratic Republic of Congo (then Zaire) and Tanzania in 1994. However, many humanitarian crises persist; conflicts can take years to resolve and the average length of stay for refugees in host countries is more than 16 years. For example, camps hosting Burmese refugees along the Thai-Burma border have been in existence since 1984, and Palestinians have been living as refugees since 1948.4 Levels of insecurity within a conflict situation fluctuate, forcing people to endure the ebb and flow of battle and resulting in recurrent episodes of flight and return. Darfur, Sudan, is a current example of an ongoing, unstable conflict setting. Humanitarian crises do not progress from one phase to the next in a linear fashion, and different scenarios may coexist in various regions of a single country. Consequently, IRC’s health programming is adapted across contexts. Table 1 describes a range of scenarios and relevant health objectives to guide interventions in such settings.

The provision of humanitarian relief is intended as a short-term input to alleviate the effects of crisis. As soon as feasible in any phase of a crisis, the emphasis of our programming shifts from provision of direct care to strengthening of local health institutions that will be able to provide for the good health of the population in the longer term.

### HUMANITARIAN CRISIS AND HIV: UNCERTAIN LINKS

The factors influencing the HIV epidemic in humanitarian crises are complex. HIV thrives in situations of poverty and inequality, which are endemic in conflict, but there is evidence as well that certain realities of conflict and displacement have had a protective effect against the proliferation of the epidemic. Our overview of the intersection

between HIV transmission and situations of armed conflict reflects Paul Spiegel’s work with the United Nations High Commissioner for Refugees (UNHCR) in exploring this question.10

One factor in conflict settings that favors the transmission of HIV is the disruption of communities that results in altered sexual networks. When a community is hit by conflict, the social structure is fractured as people follow various paths to seek safety—neighbors turn against one another to ally with opposing ethnic or political sides, and people flee in whatever direction holds the most promise. Family units are broken as some are killed, some join fighting forces, some flee, and some are separated during flight. Having fled with only the clothes on their backs and absent traditional social and family support, women, girls, and young boys may exchange sex for survival—a reality that carries with it the risk of HIV transmission.11 Another factor contributing to HIV transmission is the lawlessness that is inherent in conflict, which results in increased incidence of sexual violence. Rape has been associated with violent conflict for centuries, both as a weapon of war and as opportunistic exploitation in situations where law and order have broken down.12 Forced sexual intercourse traumatizes delicate tissues and increases the likelihood that HIV transmission will occur.13 A third factor supporting HIV transmission in conflict settings is the destruction of infrastructure and disruption of health services. People no longer have access to preventive HIV programming such as health education, care for sexually transmitted infections, safe blood transfusions, prevention of mother-to-child transmission of HIV services, or even condoms. The aftermath of conflict is also a period of increased vulnerability to HIV transmission as populations emerging from extended periods of instability have been shown to lack basic information about HIV,14 and reopened access routes bring truck drivers, migrants, and humanitarian workers from higher prevalence settings into areas previously isolated from HIV.

While several risk factors are present, other circumstances mitigate HIV transmission. Conflict zones are insecure areas where normal commerce stops and populations are isolated from exposure to external sources of the virus. Refugees benefit from humanitarian agencies that provide health information and services, including treatment of sexually transmitted infections and access to antiretroviral drugs. Returnees have better knowledge of HIV and adopt less risky behaviors than the nondisplaced.15 Isolation of populations in refugee camps or insecure areas and reduced mobility to high-prevalence urban settings also limit interactions with higher prevalence sexual networks, thereby limiting exposure to the virus.

The awareness of increased risk of HIV transmission among people affected by conflict has led to the assumption of rapid rises in HIV prevalence among people affected by conflict. However, evidence in this regard is mixed. Clearly the HIV epidemic flourished during the years of civil conflict in Uganda and declined after peace was restored to most of the country. On the other hand, despite the increased risk of HIV transmission at the individual level during rape, there is as yet no evidence that widespread incidence of rape results in increased HIV prevalence at the population level. Additionally, research in sub-Saharan Africa showed lower HIV prevalence among the camp residents in 9 out of 12 camps studied as compared with the surrounding host population (two others had a similar prevalence and one a higher prevalence).16 For example, Angolan refugees living in Namibia and Zambia were found to have a much lower HIV prevalence (5%-10%) than their host populations (25% and 15% in the areas surrounding the camps), but higher rates than in Angola (which had a prevalence of 1%-4% in areas of return).17
Although the relationships between conflict, displacement, and HIV transmission are multifaceted and require further study, key factors that influence the spread of HIV in displaced populations include HIV prevalence in country or area of origin, HIV prevalence in communities hosting the displaced population, and the degree of interaction between displaced population and surrounding communities.\textsuperscript{10}

**CHALLENGES AND OPPORTUNITIES IMPLEMENTING HIV-RELATED INTERVENTIONS**

Challenges to implementing HIV-related interventions in the setting of a humanitarian crisis have much in common with the challenges that are present in resource-limited settings generally. These include lack of sufficient numbers of qualified human resources; lack of infrastructure, equipment, and supplies; lack of financial resources; lack of leadership and accountability among public servants; and enduring denial, stigmatization, and discrimination.

Settings of conflict and displacement do, however, present some unique challenges. Staffing shortages are exacerbated as health workers are injured or killed when violence erupts. Additionally, skilled health workers, like other community members, flee the conflict and seek employment outside the conflict zone. Recruitment and retention of qualified staff who are willing to work in isolated, insecure environments is an ongoing challenge for humanitarian agencies, and governments engaged in internal conflict routinely impose bureaucratic obstacles via visa and work-permit requirements.

Shortage of financial resources dedicated to HIV programming presents a significant obstacle to addressing the disease in conflict settings. When war threatens a government, it is common to divert funding from health or other social services to shore up military forces. External donor funding for health services in humanitarian crises is provided in six-month to one-year grants—unrealistic timing for risk-behavior and stigma-reduction activities. Such short-term funding aims to deliver urgently needed minimum services but fails to respond to the reality of protracted crises where conflict and insecurity continue for a decade or more.

Logistics are another challenge, as insecurity, remote location, and ever-deteriorating road conditions impede the provision of necessary medicines and supplies.

Language and cultural differences between humanitarian staff and beneficiary populations present another notable challenge. The presence of various national, ethnic, religious, and linguistic groups in one camp requires diverse approaches to HIV-related services within a single program. For example, the population of Kakuma Refugee Camp in northern Kenya consists of Sudanese, Somalis, Rwandans, Burundians, and Ethiopians, representing Muslim and Christian beliefs as well as several languages.

The breakdown of social structures also hinders HIV care as the loss of family members results in a lack of support for people living with HIV.

For too long the assumption that HIV-positive people affected by conflict would not adhere to their drug regimen held up their access to antiretroviral (ARV) medications. At the Barcelona AIDS conference in 2002, Médecins Sans Frontières (MSF) dispelled this myth by presenting evidence of good ARV adherence by a cohort of refugees.\textsuperscript{18} Another argument for denying refugees access to ARVs was the expectation that they would likely someday return to a location where treatment was not available. However, efforts by the U.S. Bureau for Population, Refugees, and Migration along with UNHCR and IRC have built upon MSF’s work to make ARVs available to refugees worldwide. The challenge of repatriation is to provide refugees with sufficient medication for the transition period and
ensure that they are able to access HIV services at their destination point.

Despite the many challenges, HIV programming is being undertaken in humanitarian crises. In 2003, the United Nations Inter-Agency Standing Committee produced guidelines on addressing HIV in emergencies. Governments and international organizations do provide financial, technical, and direct assistance to conflict-affected populations. Humanitarian health agencies offer free health services, allowing access for people previously unable to afford care.

The presence of nongovernmental organizations (NGOs) improves the situation in other ways. Besides funding, NGOs bring technical expertise and logistical capacity. NGO programs include capacity-building activities for refugee and host country staff, thus helping to develop the health workforce. Collaboration among NGOs and government services improves the quality of care for both displaced and host populations.

Humanitarian crises can provide unique opportunities for HIV interventions. Camp populations are clearly defined, basic population data are available, and people are logistically easier to reach. The enclosed environment facilitates health education, access to services, client follow-up, and partner notification. Also, high-risk groups, such as members of the military and sex workers, may be more accessible in a crisis setting than they in a non-militarized, stable situation. During postconflict reconstruction, infrastructure and services that were inadequate before the crisis can be upgraded for the benefit of some of the most underserved people in the world.

**CASE STUDIES**

In this section we describe two of IRC’s experiences implementing HIV programs serving people affected by years of conflict in Sudan.

**Case Study One: HIV Programming during the Reconstruction Phase in Southern Sudan**

The IRC works collaboratively with returnee, IDP, and host populations in Southern Sudan striving to rebuild war-torn communities. Decades of conflict have left Southern Sudan with a dearth of qualified health workers, extremely poor transportation and communication systems, and a limited range of HIV control activities. While visiting IRC sites in Rumbek and northern Bahr el Ghazal in Southern Sudan in 2007, Susan Purdin (IRC’s health advisor for Sudan and a co-author of this chapter) helped facilitate a workshop with teachers and high school students in preparation for World AIDS Day. Participants eagerly discussed all aspects of HIV and AIDS, including voicing opinions that revealed persistent denial and stigma within the community. One teacher denied that HIV existed in the country at all, and other participants (teachers and students) suggested that HIV-positive people should be isolated from the rest of the population. While voluntary counseling and testing was being promoted, with significant numbers of people being tested, support services for people who test positive were limited. Because of intense stigma, people often disappeared after receiving positive results, and no one was participating in post-test support activities. Figure 1 shows the number of people tested in Rumbek and the cumulative total of those who tested HIV-positive from 2005 to 2007.

Unfortunately, at the time of this visit, the HIV project was funded only for prevention activities, and treatment was not available in Rumbek for those who tested positive. And, while previously offered, the supply of nevirapine for use in prevention of mother-to-child transmission of HIV had run out.

On the positive side, condoms were in high demand, and new, locally fabricated boxes dispensing free condoms were distributed widely. Education on HIV prevention was being offered through many
The IRC has provided health services in Kakuma Refugee Camp since 1992 and as of 2008 was serving more than 60,000 refugees. The camp is populated primarily by Southern Sudanese, with smaller populations from seven other countries, representing a total of 40 ethnic groups. The IRC HIV program provides a comprehensive HIV prevention, care, and treatment package. As of February 2007, more than 100 people were receiving antiretroviral therapy (ART) through the IRC clinic in Kakuma camp. HIV-positive people are referred to partner agencies for additional services such as nutritional and livelihood support.

In the interest of equity, IRC also includes the host population in HIV interventions. Initially, the community’s nomadic lifestyle and insecurity in the district made provision of services difficult.

Lessons learned in this program include the following:

- Even in a setting long-isolated by conflict, community education programs can promote the uptake of testing services despite deep-seated stigma and denial.
- In a postconflict setting, extraordinary attention is required to maintain a reliable drug supply, which is essential for sustained implementation of prevention of mother-to-child transmission programs.

Case Study Two: HIV Interventions in a Protracted Emergency—Kakuma Refugee Camp, Kenya

The IRC has provided health services in Kakuma Refugee Camp since 1992 and as of 2008 was serving more than 60,000 refugees. The camp is populated primarily by Southern Sudanese, with smaller populations from seven other countries, representing a total of 40 ethnic groups. The IRC HIV program provides a comprehensive HIV prevention, care, and treatment package. As of February 2007, more than 100 people were receiving antiretroviral therapy (ART) through the IRC clinic in Kakuma camp. HIV-positive people are referred to partner agencies for additional services such as nutritional and livelihood support.

In the interest of equity, IRC also includes the host population in HIV interventions. Initially, the community’s nomadic lifestyle and insecurity in the district made provision of services difficult.

(continued on next page)
Lessons learned from the Kakuma Refugee Camp are as follows:

- The prospect of refugee return is not a reason to limit access to ART for displaced people. Proper planning and communication ensures that returnees will be able to continue treatment.
- Working with local organizations can improve access to mobile populations and insecure areas.
- Extending services to the host community diffuses tensions between refugee and host populations and is effective in reducing the spread of HIV that results from interaction between the two populations.

IRC has worked around these challenges by funding local organizations that can more easily access insecure locations and by providing ARVs to trained members of the nomadic community for distribution to HIV-positive individuals as they travel together.

One of the challenges facing the program is the expected repatriation to Southern Sudan and the need for returnees receiving ART to continue their treatment. Efforts have been made to identify locations within Southern Sudan where ART can be accessed and this information has been provided to refugees on ART.

Preparedness and a comprehensive response. These guidelines are currently undergoing revision, primarily to update them to include the provision of ART, an intervention that should not be withheld from any medically eligible person, regardless of the setting.

Conclusion

The factors affecting HIV in conflict-affected populations are varied and complex, and the humanitarian aid associated with crisis situations brings unique opportunities to prevent the spread and mitigate the effects of the HIV epidemic. The challenge for humanitarian organizations is to understand the context, take measures to reduce the risks, and seize opportunities to provide information and services.

An effective approach to HIV in humanitarian crises involves adaptation of interventions to suit the emergency scenario, cultures of the displaced and host communities, levels of awareness of HIV, existing state of health-care systems, availability of human and financial resources, and anticipated time frame of the intervention. Experience has shown that, even with limited resources and challenging settings, quality interventions to provide HIV prevention, care, and treatment are possible and, indeed, imperative.

### A Framework for HIV Interventions in Humanitarian Crises

IRC’s HIV interventions across the various phases of humanitarian crises include a continuum of activities within a comprehensive framework. Specific activities should be introduced according to the particular phase of the crisis (see Table 2). Cutting across the framework are three key considerations: addressing the needs of survivors of gender-based violence, promoting youth-friendly services, and including people living with HIV in the planning and provision of services.

### International Standards

Despite the diversity of contexts, there are internationally agreed-upon guidelines for HIV interventions in emergency settings. The Sphere Project has published internationally recognized minimum standards of disaster response. These include minimum standards for the control of HIV (Box 1).

Mentioned previously, the Inter-Agency Standing Committee Guidelines for HIV/AIDS Interventions in Emergency Settings present cross-sectoral HIV-related interventions for both emergency preparedness and a comprehensive response. These guidelines are currently undergoing revision, primarily to update them to include the provision of ART, an intervention that should not be withheld from any medically eligible person, regardless of the setting.

### Box 1. Sphere Project Key Indicators for the Control of HIV/AIDS

The following indicators are from the Sphere Handbook, which contains recommendations for minimum standards in disaster response.

20. The Sphere Project. Humanitarian charter 
and minimum standards in disaster response. 
There is little doubt that Sub-Saharan Africa is in the midst of an HIV/AIDS emergency; children, women, and men are all caught in the crossfire of this relentless epidemic. Much attention has been paid to the impact of the epidemic in this region on women, sex workers, young people, and other vulnerable populations; but research and interventions targeting men who have sex with men (MSM) have been conspicuously absent. According to a 2007 report from the International Gay and Lesbian Human Rights Commission entitled “Off the Map,” there are a number of troubling explanations for this lack of response on the part of key HIV/AIDS stakeholders, including homophobic stigma and denial; restrictive international reproductive health policies; the mixed record of international and domestic nongovernmental organizations with regard to responding to the needs of same-sex-practicing people; the lack of sufficient skills and resources among lesbian, gay, bisexual, and transgender organizations in Africa; and the lack of political space in which to effectively advocate for access to HIV-related services and other health-related human rights at the domestic, regional, and international levels.¹

At a meeting of Schorer (the Dutch gay and lesbian health service provider) in September 2007, a number of civil society organizations, policymakers, and researchers came together to highlight the absence of appropriate research targeting MSM (and women who have sex with women, WSW) in the context of HIV/AIDS. The questions that arose were not only concerning the absence of data on HIV infections among these categories of vulnerable populations, but also the absence of an understanding of appropriate, evidence-based preventive measures. Similar questions emerged at an international meeting of key stakeholders working in the area of gender, same-sex sexuality, service delivery, and health in Pretoria, South Africa, in May 2007.²

No discussion of HIV/AIDS is possible without consideration of the issues that shape its interpretation and meaning, such as sex, sexuality, and disease. These related concepts are themselves often subject to a variety of misconceptions and stereotypes. The brief discussion presented here offers some perspective on these issues (within the context of HIV/AIDS) as well as the concept of homossexuality as it relates to the HIV epidemic in sub-Saharan Africa.
TERMINOLOGY: SEX, SEXUALITY, AND DISEASE

Sexuality, while viewed by many as an intimate, personal domain, is in actuality regulated and policed by many powerful external forces, including culture, politics, law, religion, and commerce. Activism related to sexuality is primarily in response to political will being exerted over people’s expression of their sexuality, a common struggle in many countries around the world. For instance, the drive to decriminalize certain sexual orientations or sexual practices in Africa and elsewhere has given rise to a number of organizations to promote sexual diversity and the human rights of lesbians and gays (e.g., the Lesbian and Gay Equality Project in South Africa, the Gay and Lesbian Coalition of Kenya, and Rainbow Project in Namibia).

Sex, broadly defined, is a way of categorizing humans that “divides them into biologically based categories—male or female.” Sexuality, in turn, is defined as “a set of social processes that produce and organize the structure and expression of desire.” When the abstract concept of sexuality moves toward tangible expression—that is, through sexual acts, sexual behaviors, and sexual choices—social constructs begin to take shape. Today we increasingly witness the impact of HIV/AIDS on how we negotiate our sexuality and our sexual activity. For instance, the emergence of HIV/AIDS has resulted in the resurgence of associations of sexuality with disease. Consequently, the medical community’s interest in sexuality is expanding to new areas beyond the traditional specialties of sexually transmitted infections, obstetrics and gynecology, and psychiatry.

HOMOSEXUALITY

Much like race, sexuality is a marker of fundamental differences. The feminist movement’s critique of patriarchy, the gradual liberation of gay and lesbian people around the world, and the impact of HIV/AIDS have all contributed to an understanding of sexuality as less of a social and moral “line in the sand” than a continuously debated source of identity and meaning.

In South Africa for example, homosexuality has enjoyed a renewed acceptance since the fall of Apartheid. The transition from the criminalization of homosexuality under the Apartheid government to the equal rights of gays and lesbians under the constitution created by the ruling African National Congress represents a considerable step in the right direction. Yet despite these protections (known as the “Equality Clause”) of individuals against unfair discrimination due to their sexual orientation, it remains to be seen whether these clauses will be fully supported by governmental action.

One issue that is emerging in many different political and social contexts is the consideration of sexuality as a human rights issue. Sexual difference, and in particular, homosexuality, has been used as the basis for criminalization, exclusion, and marginalization around the world. Often discrimination of homosexuality has been fueled by its relation to HIV/AIDS, as was seen in the early years of the epidemic and continues to be the case in many countries (e.g., Namibia, Botswana, and Zimbabwe) where a lack of access to information, along with discrimination in provision of basic services, puts lesbian, gay, bisexual, and transgender people in the region at particular risk both of contracting HIV/AIDS and of suffering disproportionately from its medical consequences.

HIV/AIDS AND MEN WHO HAVE SEX WITH MEN

First identified in the early 1980s by doctors who were seeing homosexual men dying without explanation, AIDS was initially termed GRID (gay-related immunodeficiency). Only in 1984 was the term AIDS (acquired immune deficiency syndrome)
HUMAN RIGHTS AND HIV CARE

officially taken up by the medical establishment. Despite this early correction, the myth that AIDS is a gay-related disease still prevails in many settings.

The phrase MSM, while not new, is certainly new to many parts of the world. This phrase broadly describes men who lead different lives in different contexts. Like any label, it is not an inconsequential designation; it has a history, makes assumptions, and conveys complex suggestions about how sexuality is framed by those who use it. Essentially, it is used to focus attention on sexual acts, providing a way to communicate about or speak about safe sex practices, without committing to culturally coded identities (e.g., gay, lesbian, bisexual).

In sub-Saharan Africa, there are virtually no programs to combat HIV/AIDS and violence specifically among MSM and WSW. This is at least in part due to the tenuous legal situation of MSM in many African countries, several of which have laws criminalizing same-sex conduct, often termed “sodomy laws” (Figure 1). Because data on MSM and WSW populations are sparse, governments, donors, and civil society organizations need to develop policies and programs for all sexual minorities (not just those who self-identify as gay, lesbian, or bisexual).

Although there is a great need for interventions targeting these often marginalized or hidden populations, many obstacles stand in the way of progress. HIV prevention programs for MSM are hindered by many factors, including (1) denial at all levels that same-sex relations take place; (2) stigmatization and/or criminalization of MSM; (3) inadequate or unreliable epidemiological information on HIV transmission through male-to-male sex; (4) difficulty reaching MSM, especially those who do not self-identify; (5) lack of awareness or sensitivity among health facility staff about the existence or needs of MSM; (6) reluctance on the part of donor agencies to support prevention programs among MSM; and (7) lack of attention in national AIDS strategies to the needs or existence of MSM. (It should be noted that the government of South Africa, after much lobbying and advocacy, finally included vulnerable groups such as MSM in its current National Strategic AIDS Plan.)
Innovative approaches to overcome these barriers are essential so that informed, qualitative research on MSM can assist in better addressing the needs of this population.

Some issues to consider regarding the conducting of research with MSM are as follows:

- MSM are a diverse group, and there is diversity in expression and organization of homosexuality. In order to develop effective interventions, there is a need to understand the diversity that exists within this population.
- HIV risk cannot be understood and effectively addressed without taking other issues into account (e.g., stigma, discrimination and violence, alcohol and drug use, socioeconomic and cultural circumstances).
- Effective research requires involvement of affected communities; outcomes of research should be shared with the community in the appropriate format.
- The usefulness and efficacy of MSM as a concept may change over time.

**Prevalence of HIV Infection Among MSM**

It is difficult to know the prevalence of HIV infection among MSM in developing countries for a number of reasons. First, due to a number of causes including lack of political support, very little research has been done that focuses on the prevalence of HIV infection in this population and the characteristics of infected or at-risk men. Second, there are methodological challenges: It is practically impossible to recruit representative samples of men who engage in same-sex relationships. This implies that when prevalence data are reported for this population, it is always important to examine how the men were recruited into the study (i.e., is participation based on self-selection or a somewhat random recruitment strategy). Eligibility criteria for participation in the study must also be looked at carefully—did

---

416 FROM THE GROUND UP: LAYING A STRONG FOUNDATION
men have to self-identify as gay, or was a wider net cast and was involvement in homosexual sex the criterion? Also, it is important to know the channels that were used for recruitment and to what extent these channels promoted diversity among men in the sample or whether homogeneity was a factor. Yet despite these considerations, valuable research can be conducted. Baral and colleagues reviewed available studies and showed that in Kenya, Senegal, Sudan, and Egypt the observed prevalence of HIV in MSM was 1.6 (Kenya) to 108.9 (Egypt) times as high as in the general population. Van Griensven concluded that the high HIV prevalence among MSM from Kenya, Senegal, and Sudan was remarkable: While adult HIV prevalence in Kenya recently declined to an estimated 6.1%, and adult HIV prevalence in Senegal and Sudan is estimated to be 0.9% and 1.6%, respectively, the prevalence observed among MSM in these countries was 10.6% (Kenya), 21.5% (Senegal), and 9.3% (Sudan). Although

**International Gay and Lesbian Human Rights Commission (IGLHRC) calls upon the governments of African nations to—**

- Repeal all laws that criminalize same-sex consensual conduct in keeping with international human rights law. These laws contribute to HIV vulnerability for same-sex-practicing people by driving them underground and supporting their marginalization. End arrests, harassment, and persecution of people on the basis of sexual orientation in countries that have no antihomosexuality laws.
- Prosecute physical and verbal attacks, expulsion from schools and housing, and other forms of harassment, persecution, and abuse of same-sex-practicing people. Extend the equality provisions of national constitutions to include sexual orientation. End impunity of law enforcement officials and private individuals for homophobic discrimination and violence.
- Build relationships with local lesbian, gay, bisexual, and transgender (LGBT) and sexual rights organizations and provide funds for the scaling-up of successful HIV prevention, voluntary counseling and testing, treatment, and care programs for same-sex-practicing people through direct government grants and contracts. Work collaboratively with organizations that have experience implementing such programs.
- Make condoms, dental dams, and latex-compatible lubricants available in jails and prisons; offer comprehensive HIV prevention education to people who are incarcerated.

**IGLHRC calls upon the United States government to—**

- Launch requests for applications in Africa specifically for HIV prevention, care, and treatment programs for men who have sex with men and women who have sex with women. Ensure that successful applicants have experience implementing similar programs, preferably in Africa, and that they partner with local LGBT organizations.
- Fund a comprehensive study of HIV transmission between women and the HIV vulnerabilities of same-sex-practicing women in Africa.
- Stop the exportation of homophobia by removing restrictions on international reproductive health funding that increase stigma against sexual minorities. Rescind the Mexico City Policy (Global Gag Rule) and the requirement of the Prostitution Pledge. Modify the implementation of the ABC approach to eliminate the supremacy of abstinence-only until marriage programs. Promote comprehensive HIV-risk-reduction education.
- Include lubricants and dental dams as supplies that can be funded under the President’s Emergency Plan for AIDS Relief and other U.S. funding programs. Ensure that condoms are readily available for distribution by governments and nongovernmental organizations (NGOs) without complicated warnings of their supposed ineffectiveness.
### Box 1. Summary of Recommendations from the 2007 International Gay and Lesbian Human Rights

**IGLHRC calls upon the United States government to (cont.)**
- Create a small grant fund with which African LGBT organizations can implement HIV pilot projects; provide organizational and programmatic capacity building in the form of training and technical assistance to increase the success of these initiatives. Use these projects to gather information on the effectiveness of various techniques and strategies for decreasing HIV transmission among same-sex-practicing people.

**IGLHRC calls upon foreign governments, foundations, and corporate donors, including the United States, to**
- Increase funding to African government agencies and international and local organizations ready to implement programs for same-sex-practicing people in Africa. Encourage grantees implementing broad-based HIV public education campaigns to investigate the needs of same-sex-practicing people and adjust their approaches to be more inclusive.
- Refrain from funding any project or organization that openly discriminates against LGBT people or preaches hate against anyone due to their membership in the social categories protected by the International Covenant on Civil and Political Rights.
- Fund a comprehensive study of HIV transmission between women and the HIV vulnerabilities of same-sex-practicing women in Africa.

**IGLHRC calls upon private voluntary organizations working against HIV/AIDS in Africa to**
- Undertake appropriate consultations with LGBT organizations and leadership in Africa, as quickly as possible, in order to jointly launch HIV prevention, treatment, and care programs that specifically target same-sex-practicing people.
- Ensure that same-sex-practicing people are not excluded from the messages contained in generalized HIV/AIDS public education programs. Promote images of individuals and their relationships that are representative of the broad spectrum of human sexuality.
- Work with country-level staff to develop policies that promote equality and respect for same-sex-practicing people who access programs and services.
- Staff programs that target same-sex-practicing individuals with self-identified same-sex-practicing people. Make training opportunities available to help these individuals to adequately fulfill their roles. Offer them adequate and appropriate support to withstand the homophobia they are likely to face from within and outside the organization.

**IGLHRC calls upon domestic AIDS service organizations working against HIV/AIDS in their countries to**
- Develop policies that promote equality and respect for same-sex-practicing people who access programs and services.
- Ensure—through invitations, advertising, community fora, promotional materials, and other means—that same-sex-practicing people are welcome participants in organizational programs and events. Reach out!
- Assist LGBT organizations in designing and managing AIDS prevention, care, and treatment programs to serve their own communities. Partner with LGBT organizations to access funding and implement HIV programming for same-sex-practicing people and LGBT communities.
- Increase the availability of condoms, including female condoms. Ensure that latex-compatible lubricants and dental dams are part of standard “safer-sex kits” available to all recipients.

---

418  FROM THE GROUND UP: LAYING A STRONG FOUNDATION
seroprevalence studies in South Africa are still under way, preliminary findings suggest that HIV prevalence among MSM is in the same range as the general population. What these studies also show is that same-sex sexuality is part of the sexual repertoire of African men, regardless of its legal status.

**SUMMARY**

A number of possible strategies to better address HIV among MSM have been identified (see Box 1). It is up to all stakeholders to help move us toward a more inclusive model of HIV/AIDS programming that takes the needs of all affected populations into account, regardless of how marginalized or “hidden” they may be. Although legislation protecting the rights of individuals, regardless of sexual orientation, and the rescinding of laws criminalizing same-sex conduct are steps in the right direction, they are only the first step. As has been observed in South Africa and elsewhere, additional steps must be taken to ensure that appropriate actions are taken by both government and nongovernment actors to enforce and protect the rights of MSM and other marginalized groups. Only in this way will we succeed in conducting meaningful research and developing interventions that can succeed in combating the epidemic among MSM and other same-sex-practicing people.
REFERENCE LIST

Noerine Kaleeba in front of her home in Uganda.
IN THE STORIES OF THE breakthroughs in the AIDS fight, Uganda is often cited as a birthplace of change. But in 1986, when Noerine Kaleeba’s husband, Christopher, learned he was HIV-positive, even their closest friends shunned them.

Kaleeba remembers one Sunday that year when she, her husband, and their four young girls—ages 8, 7, 5, and 3—slid into their regular pew at All Saints Church in Kampala, the nation’s capital. Just as they sat, others around them stood and left.

“It’s very difficult to believe that happened in Uganda, but it did happen,” Kaleeba said.

That affront, still remembered clearly more than two decades later, propelled Kaleeba onto a path of activism. Her husband died the next year. She remained HIV-negative, surprising her doctor, who had never before heard of a discordant couple—

written by John Donnelly
photographs by Dominic Chavez
with one partner infected, the other not. Kaleeba remembered the doctor telling her at the time, “We don’t know what’s going on. The virus doesn’t seem to show up in your blood.”

That same year, Kaleeba, a physiotherapist by training, helped start a support group in Uganda for those infected and affected by the virus. The group became The AIDS Support Organization, or TASO, which grew so surely and strongly that it soon was a model for the rest of the continent and beyond.

She sees all her work growing out of how she initially reacted to rejection. “It was an act of self-preservation because we were so stigmatized and so alone,” she said. “When I met other people going through the same problems, I knew I was not isolated, and I decided I will not take this lying down. I decided I will set up a visible process where people could be cared for and have their health restored and have their dignity restored.”

Kaleeba, now 56, had ambitions outside Uganda. After eight years as TASO’s executive director, she joined UNAIDS in Geneva as partnership and community mobilization adviser. Organizations bestowed awards and honorary degrees upon her. Groups corralled her to sit on their boards. She became known internationally for not mincing words about problems facing fellow Africans. But in 2005, she was ready to return to her African roots, first to Malawi and then to her native Uganda, to work on issues affecting women and children.

She seemed happy to be back in Africa. “I love being with people,” she said outside her Malawi office. “I love sitting with them as they do their planning, day by day, walking the journey with them.”

In Uganda, friends call her Mama Kaleeba. It fits her well. In 2007, she was supporting 38 children, almost all of them orphans.

“For us, to lament the plight of orphans, to talk about it, to write about it, and not doing something concrete—well, for us, that is not an option,” she said.

Her new mission, though, has been trying to slow the tide of children orphaned by AIDS deaths. “You can provide school fees and food for orphans, but if you ask the children what they want, they want Mom and Dad. So my part is to keep the parents alive. As long as they are alive, those children are not orphans.”

“To lament the plight of orphans, to talk concrete—well, for us, that is not an option.”
Q: What are the current challenges now in the fight against AIDS?
“I have always believed the response to HIV/AIDS should center on the people impacted the most. For Africa, it means the poor, the women, and the children. When you look at the programs, it doesn’t focus on that. We still are planning very generalized responses. We are not addressing the root causes of the problem. One of them is that women don’t have sufficient education. We are not addressing the central issue of poverty. A woman who has no access to money will not be able to take a bus to a clinic. It doesn’t matter how much money we pour into the clinic if women can’t get there.”

Q: How would you change the programs?
“I would put more resources and efforts with the village chief, the traditional healer, the small Christian or Muslim leader—the ones we know reach grassroots. I also would get better information to the local health worker. On an international level, we have even glamorized the work they do, but we haven’t put any effort into really teaching them. In many communities in Africa, the health workers are still churning out the same old false stories about HIV that they did 20 years ago.”

Q: What will be the biggest challenge in five years?
“The challenge will be still to work toward a day when there is community conversation about the impact of HIV, when there are basic conversations in a village. Now we talk about AIDS in AIDS workshops, in a meeting somewhere. Only rarely do women talk about it when they fetch water from a well. This silence in villages fuels HIV, and the feelings of shame and stigma that go with it.”

Q: How do you get people to talk about HIV at a waterhole?
“From my experience it’s a combination of things. There has to be a high degree of political openness arising from the political leaders, the heads of state. You should also have openness at the community level, in households. You need to get traditional leaders, people living with HIV, or families affected by HIV/AIDS to begin articulating their own issues and how AIDS has impacted them. And lastly, you also need international solidarity. Uganda would not have been able to do what it did without international solidarity. It’s not just about money, but it’s also about starting scientific studies that educate us. All of that leads to reduced stigma and learning more about the path of this virus.”
“I feel happy to see this photo. These children didn’t refuse when I asked if I could take a picture of them. It made me laugh, which does me good.”

About the Artist
Cecilia lives with her grandmother and older brother; their parents died of AIDS when Cecilia was very young. Her brother, Serge, runs a small business, providing the family with some income. Contributions from Reencontro, a local NGO, also help make ends meet.

Cecilia loves school. She walks 30 minutes each way to school every day and hopes to be a director of a school when she grows up. Many of her concerns are with her family and home because the roof of the house leaks when it rains and she worries about her grandmother’s health.

Introduction to Volume II: Establishing a Framework for Success

It is essential that HIV/AIDS programs are based upon the most up-to-date, sound clinical and scientific evidence and practical experience. There are numerous, and often disparate sources of information to be drawn from in the field of HIV/AIDS, often making it hard to ensure that programs are thoroughly evidence-informed. Yet we must always strive for the highest possible standard of care, while ensuring that we take into account the wide spectrum of services that constitute a truly comprehensive approach. The AIDS pandemic represents a formidable challenge for the medical, nursing, and allied health communities, one that we will not conquer for some time. Yet the numerous brilliant minds dedicated to this cause have taken us further than was previously thought possible, giving us remarkably effective treatments and preventive interventions, and providing insight into the most complex facets of this disease.

This second volume starts off with the section “Science and Treatment of HIV Infection,” which provides a brief overview of the characteristics of HIV infection and the basics of antiretroviral treatment. Here we will learn about the geographic variations of the virus, as well as the immune response and the effect of antiretroviral treatment on this response. We are also reminded that when we treat someone living with HIV, we are treating the whole person, not just one disease. Therefore we must take into account a range of other health needs, such as treatment for tuberculosis, malaria, and hepatitis. Two sections in this volume, “Opportunistic Infections, Cancers, and Coinfections” and “Prevention and Management of Tuberculosis,” discuss the identification and management of these and other life-threatening conditions in HIV-positive individuals, and how the associated heightened risks from coinfection and co-treatment can be minimized.

A largely unmet need also exists for psychosocial support for people living with and affected by HIV. Counseling is a powerful tool at our disposal that can be used to both prevent new infections, and to support those living with and affected by HIV. The chapters in the section “HIV Prevention, Counseling, and Testing” show us that it is within our power to equalize the balance between prevention and treatment in order to stem the tide of new infections. Prevention has lagged behind treatment, a trend that must be reversed in order for us to make headway in combating the global pandemic. Some of the methods proposed by the authors in this section include greater integration of prevention into care and treatment programs, the creation of prevention interventions targeting people living with HIV, and the use of innovative counseling and testing strategies.

Rounding out this volume are the sections “Prevention of Mother-to-Child Transmission of HIV” and “Pediatric and Adolescent HIV Care”. These two sections outline the critically important steps we can take to stop the spread of disease to newborn infants, and to manage infection in young people—a highly vulnerable and often overlooked group. Chapters focus on a range of important issues, from drug selection for prevention of mother-to-child transmission and methods of early infant diagnosis, to experiences establishing youth-friendly health services.
Ultimately the success of our programs will be measured not only by how many people we enroll into care and treatment, but also by our ability to prevent new infections and provide quality services to all those in need, especially the hardest-to-reach populations. If there is one theme that runs throughout the diverse chapters featured in this volume, it is that no health condition can be managed in isolation, and no individual, regardless of age or gender, can attain long-term health without receiving a comprehensive range of services that respond to their medical as well as their psychosocial needs. Based on this assertion, it could be said that true success will be conditioned upon our ability to apply a programmatic framework that encompasses, and is able to link together, all of these disparate but inextricably linked services at all levels of care—from the health facility to the community.

Michel Kazatchkine

Michel Kazatchkine, M.D., executive director of the Global Fund to Fight AIDS, Tuberculosis, and Malaria, has spent the past 20 years fighting AIDS as a leading physician, researcher, administrator, advocate, policymaker and diplomat. Throughout his career, Dr. Kazatchkine has been closely involved with national and international NGOs working in the field of health and development. He is a long standing member of Médecins du Monde and a founding member of Nova Dona, an NGO providing services to drug users in Paris.
SAM PHIRI GREW UP in a rural village in Malawi among farmers who scratched out a living from the land. That was what people did there, generation after generation. There was little in his upbringing that would suggest he would move beyond secondary school. But Phiri, who is executive director of the Lighthouse Clinic, Malawi’s first AIDS treatment center, was driven to do community service. And he found that he had a strong interest in medicine.

He said his religious upbringing also guided him. His mother, he said, taught him that their Christian faith meant “we should be caring for others.”

“Even now, my mother and I do not talk about what exactly that I do,” Phiri said. “Instead, she says to me, ‘Son, do you make sure your skills as a Christian are assisting your patients?’”

The son always tells his mother he is. Phiri, a
DR. PHIRI TENDS TO ONE OF HIS PATIENTS AT THE LIGHTHOUSE CLINIC IN LILONGWE, MALAWI.
“With ARVs coming in, we finally have treatment. But scale up strategies on behavior change.”

medical clinician who is working on his PhD at the London School of Hygiene and Tropical Medicine to become a clinical epidemiologist, has been treating AIDS patients since 1993. For many years, the situation seemed hopeless; hospitals were swamped with AIDS cases—one 1997 study in Malawi found that 73% of the adults hospitalized with a fever were HIV-positive—and treatment options were all poor.

Many times, over several years, Phiri and his colleagues despaired at the rate of death from AIDS. “The corridors of the hospital were full, the verandas were full, and then they would leave the hospital very, very sick,” he said. “We had no way of following up on these patients who returned to their homes. I’m sure most of them died.”

In 2002, he helped found the Lighthouse, which would not only usher in an era of antiretroviral medicines to people infected with HIV, but also give those patients specialized care that was lacking in hospitals. Phiri and several friends chose the name Lighthouse because to them it represented a “beacon of hope—even though Malawi is a landlocked country,” he said, laughing.

In his job, Phiri, 42, has mostly served as an administrator, although he saves one day a week to see patients. “I am a clinician at heart,” he said. “I don’t want to lose that because it is so satisfying to see a patient, manage their care, and watch them improve.”

The Lighthouse has grown steadily in its first years, and by the end of 2007, it was overseeing the antiretroviral treatment of 5,000 patients. The clinic also was counseling and testing roughly 2,000 people a month. And it is helping train a new cadre of health workers in Malawi to treat people with HIV. Nearly three-quarters of Malawi’s health workers who see AIDS patients were trained at the Lighthouse. Sitting in his office at the clinic, Phiri reflected on the beginnings of the Lighthouse and its future.
Q: What was the genesis of the Lighthouse?
“I remember it well—it was 1996. I was working in the central hospital (in Lilongwe), and the adult wards were really full. I said to myself, ‘What is really going on? Isn’t there anything I can do?’ We had a problem with the drugs, and a lot of people were dying. On top of that I lost some friends in the medical department.”

Q: Do you recall one death in particular?
“Yes, it was the death of one of my colleagues—a close friend. He opened up quite late, that he had AIDS. By the time he confided in me, he was really not well. But there was more to it. He had meningitis and we did not have the best medicine for it. I said then that we really could have done better.”

Q: When did you know that the Lighthouse was going to work?
“Just after we opened it in 2002, we had a group education session for many patients. We wanted to give them general HIV information. Stigma was very high. People didn’t talk about having AIDS. But at that meeting, I was shocked that people stood up and said, ‘I found out I was with HIV and I was told I could come here to be assisted. How can you help?’ I knew then that the clinic was going to be busy, and that it was going to be hard work.”

Q: For a while, the number of patients began to overwhelm staff. How did you deal with that situation?
“By 2005, we were seeing over 250 people a day. We decided to limit that to 180 patients. It was difficult, but we had to do it. It was first come, first served. By 7 a.m., we were registering 180 patients. Then we adjusted our system: nurses took care of some patients, and patients who were well would come every two months, not every month.”

Q: What are the challenges you’ll face in the next five years?
“We will not have a problem in finding enough people to put on treatment. The problem is how we cope with the demand. The government’s goal in Malawi is to have 245,000 patients around the country on treatment by 2010. With more people on treatment, we’ll also have more side effects, and more resistance. So doctors may need to do more clinical work with individual patients. That means we will have to focus on capacity building and improving service delivery.

“The other big change deals with prevention and behavior change. With ARVs [antiretroviral drugs] coming in, we finally had treatment. But now people may go back to loose behaviors. We need to scale up strategies on behavior change.”
SCIENCE AND TREATMENT OF HIV INFECTION
HUMAN IMMUNODEFICIENCY VIRUS types 1 and 2 (HIV-1 and HIV-2) are members of the Lentivirus genus of the Retroviridae family of RNA viruses and are 50% similar at the genetic level. HIV-2, although more closely related to the simian immunodeficiency virus (SIV), is the second human immunodeficiency virus and constitutes the closest known human virus related to the prototype AIDS virus, HIV-1. HIV-2 shares many virologic and biologic features with HIV-1. Like other retroviruses, both HIVs induce lifelong infection, with permanent integration of viral genetic material into the host cell's DNA. The enzyme responsible for viral replication, reverse transcriptase, is error-prone, which results in considerable genetic variation. This variation is more pronounced in the genes that encode the outer envelope regions compared with the polymerase (pol) and group-specific antigen (gag) genes, which are more genetically constrained from variability. Both HIV-1 and HIV-2 enter susceptible cells via the same primary receptor, the CD4, but secondary co-receptors may differ between the two viruses. As a result of these similarities in cell receptors, both viruses are transmitted by the same routes and infect the same cell types in people.

HIV-2
Although HIV-1 and HIV-2 are highly related lentiviruses, they maintain some distinct epidemiologic and biologic characteristics. HIV-2 is largely confined to West Africa, while HIV-1 infection is prevalent worldwide and accounts for approximately 95% of all HIV infections globally. Importantly, disease progression to AIDS occurs much more slowly in HIV-2. In comparison to HIV-1, these biologically relevant characteristics of HIV-2 infection in vivo appear to model those of an attenuated HIV infection. To date, the precise mechanisms responsible for this attenuated phenotype of HIV-2 remain unclear. However, HIV-2, like HIV-1, causes AIDS, although more slowly, and it was based on these initial similarities that some believed that HIV-2 might cause a second worldwide AIDS epidemic. Now, 23 years after the discovery of HIV-2, no such epidemic has occurred. Rather, research studies conducted both in the laboratory and in HIV-2-infected people in West Africa have highlighted distinct biological differences between these related viruses.
History and Distribution of HIV-2 in Africa

It is now recognized that HIV and closely related viruses in primates, termed SIVs, exist. The close antigenic relatedness of both SIV and HIV-2 to the prototype HIV-1 virus prompted both the discovery and further classification of these related viruses.\(^3\)\(^-\)\(^5\) When sera from West African female sex workers were screened for antibodies to HIV-1 antigens, the antibodies revealed extensive cross-reactivity for the virus gag antigens but minimal antibody binding reactivity for the HIV-1 envelope.\(^3\) Yet, when the same West African human sera were assayed on SIV antigens, they reacted strongly with the envelope proteins as well as the gag antigens, suggesting infection with a virus that was more closely related to SIV than to HIV-1. As more sequence data became available from various HIV-2 and SIV strains, it has also become apparent that no branching order of divergence can be identified and that HIV-2 and SIV most probably share a common ancestor.\(^6\)\(^-\)\(^7\) Therefore, it is well recognized that HIV-2 is more closely related to SIV than to HIV-1. As estimated that the HIV-1 and HIV-2/SIV groups of viruses might have diverged from each other as recently as 50–60 years ago.\(^8\)\(^-\)\(^9\)

The discovery of HIV-2 in Senegal, West Africa, in the mid-1980s prompted numerous studies to determine the geographic distribution and biological significance. Through the use of type-specific serology assays, we now recognize that HIV-2 is prevalent in most West African countries, surprisingly a distinctly different worldwide distribution compared to that of HIV-1.\(^10\)\(^-\)\(^12\) In most other countries of West Africa, such as Burkina Faso, Ghana, Ivory Coast, Nigeria, and Mali, infection with HIV-1 is more prevalent than infection with HIV-2, ranging from a 3- to 24-fold rate ratio (HIV-1 versus HIV-2).\(^13\)\(^-\)\(^18\) Although recent national serosurveys have not distinguished these virus types, it is widely considered that HIV-2 prevalence rates are diminishing. This supports the hypotheses raised by Anderson and May, who analyzed the available biological and epidemiological data on HIV-1 and HIV-2 and used simple mathematical models to study the competition between the two viral types.\(^19\) The mathematical model of the concomitant transmission of the two viruses within the same sexually active population suggested a positive association between pathogenicity and reproductive success, indicating that HIV-1 would competitively displace HIV-2 in the long term. In our study of both viruses in Dakar, Senegal, over the past 20 years, we have also observed the decrease of HIV-2 prevalence in registered sex workers and a concomitant increase in HIV-1.\(^20\)

Outside West Africa, sporadic reports of HIV-2 infection have been previously made in Portugal, Mozambique, Angola, southwestern India, and Brazil; these events are all related to the former ties Portugal had with West Africa.\(^21\) Portugal itself appears to have low but stable rates of HIV-2 prevalence in the population.\(^14\) The other countries once shared common historical-political ties, with some economic trade relationships existing even today. As noted, HIV-2 has been detected in some large cities in southwestern India,\(^22\)\(^,\)\(^23\) perhaps because of exchange with the former Portuguese colonies of Africa. Goa, a former Portuguese colony, situated south of Bombay on the western coast, has reported 4.9% HIV-2 and 9.8% HIV-1 infection rates in patients with sexually transmitted infections (STIs).\(^22\) To date, significant HIV-2 infection has not been reported in other parts of Asia.

HIV-2 Laboratory Diagnosis

The close relationship of HIV-2 to HIV-1 on a genetic and antigenic level has necessitated the development and use of type-specific assays in order to diagnose and distinguish these related viruses. The same methodologies and technologies...
for HIV-1 serologic testing, virus culture, and genetic diagnostics such as polymerase chain reaction (PCR) have been modified for HIV-2 diagnosis and improved over the years. Because most of the original HIV antibody tests were developed using HIV-1 antigens, the degree of cross-reactivity and specificity for HIV-2 was highly variable. Most of the first-generation tests used whole virus antigens, where antigens such as p24gag and pol proteins (p66/p51) were well represented. These antigens are more strongly cross-reactive between HIV-1 and HIV-2 compared to the envelope antigens, especially the external envelope protein, the gp120. In the early 1990s, most European nations, followed by the United States, incorporated HIV-2 testing into blood bank screening. The antibody tests used were Enzyme-Linked ImmunoSorbent Assays (ELISAs) with combined antigens of HIV-1 and HIV-2. Confirmation of HIV-2 serostatus requires an HIV-2-specific immunoblot (Western blot) or specific peptide assays. Immunoblots demonstrating a profile of major structural gene product recognition are typically used to confirm HIV-1 and HIV-2 diagnosis using standard criteria. HIV-2-specific diagnosis by immunoblot requires antibody reactivity to env + gag + pol antigens. In the absence of reactivity to gag or pol antigens, the presence of reactivity to two envelope antigens is required (gp120 and gp32, transmembrane protein).

Various investigations have focused on identifying type-specific antigens to allow confirmatory tests that will distinguish between HIV-1 and HIV-2. Most have been made as synthetic peptides, but some were larger bacterially expressed peptides which vary in sensitivity and specificity. As most were selected for specificity, one might expect that sensitivity could be compromised. Thus, although appropriate for type-specific confirmation, they may not be as useful as larger HIV-2-specific antigens for initial screening.

The various type-specific assays can yield a result of HIV-1 and HIV-2 positive status. The HIV dual antibody profile is characterized by antibodies with strong reactivity to the env antigens of both HIV-1 and HIV-2 by immunoblot and/or radioimmunoprecipitation analysis (RIPA). This may result from the extensive cross-reactivity that exists between the viruses and the lack of type-specificity of the assay employed. Several possible biologic explanations for this phenomenon can also be entertained, including dual infection by both viruses or infection with a recombinant virus. When human serum samples were tested in places such as Ivory Coast, Senegal, and Burkina Faso, a disproportionately large fraction of the samples often tested as “dual positive” because they appeared reactive on both HIV-1 and HIV-2 confirmatory tests. These sites have significant rates of both HIV-1 and HIV-2 infection, and distinction of viruses and designation of dual reactivity remains a diagnostic challenge for the typical HIV laboratory in geographic locales where both viruses are circulating. When rates of HIV-2 virus infection in a region or study have been low or absent, it is generally considered that the finding of dual HIV-1/HIV-2 infection is erroneous and likely due to cross-reactivity from HIV-1 infection alone.

**Lowered Sexual and Perinatal Transmission Rates**

Although HIV-1 and HIV-2 are thought to be transmitted through human populations by the same modes of transmission, the epidemiologic distribution suggests that the rates of these transmissions may be distinct. In West Africa, the spread of HIV-1 has exceeded that of HIV-2 over the past two decades. During an eight-year period of follow-up in Senegal, there was a 26-fold increase in HIV-1 infection rates, whereas HIV-2 infection rates remained relatively constant. These studies indicated that HIV-2 may have been in the human
population in Africa at least as long as HIV-1, and in West Africa, HIV-2 has apparently been present considerably longer. The relative lack of significant HIV-2 prevalence in Europe, North America, and Asia in the face of HIV-1 expansion also supports the general notion that HIV-2 is spread less efficiently than HIV-1.21,42-48

HIV-2 infection transmitted by blood and blood products has been reported in case reports; however, widespread HIV testing in blood bank settings has most probably limited the risk of this mode of transmission.45,50 The most common modes of HIV transmission in HIV-2-endemic areas are perinatal and heterosexual transmission; since most West African countries have been afflicted with both HIV-1 and HIV-2 infections, direct comparison of transmission rates between the two viruses has been possible. In Senegalese female sex workers followed over an 11-year period, the annual incidence of HIV-1 dramatically increased, with an 18-fold increase in risk per year and a 13-fold increase in risk over the entire study period. By contrast, the incidence of HIV-2 remained stable, despite higher HIV-2 prevalence.10,41 In this high-risk group, the heterosexual transmission of HIV-2 was significantly slower than that of HIV-1, which strongly suggests differences in the heterosexual transmission potential of these two related immunodeficiency viruses.

Gilbert et al performed a modeling study of HIV-2 and HIV-1 to compare transmission potentials, where new nonparametric competing-risks failure-time methods were used, which minimized modeling assumptions and controlled for risk factors for HIV infection. Observing 1,948 women followed from 1985 to 1999, we compared the male-to-female transmission probability of HIV-1 and HIV-2 per infectious sexual exposure. The HIV-1 versus HIV-2 infectivity ratio over time was estimated by nonparametric kernel smoothing of the HIV-1/HIV-2 infection hazard ratio in sex workers adjusted by an estimate of the relative HIV-1 versus HIV-2 prevalence in the partner population. HIV-1 was found to be significantly more infectious than HIV-2 throughout the follow-up period (P<.0001). The HIV-1/HIV-2 infectivity ratio was inferred to be approximately constant over time, with an estimated ratio of 3.55.51

Maternal or perinatal transmission of HIV-2 also appears to be less efficient than for HIV-1.52-57 Perinatal transmission of HIV-2 and HIV-1 has been studied in Guinea Bissau, Ivory Coast, France, and Senegal, with all demonstrating extremely low rates of perinatal transmission of HIV-2 (0%–3.7% transmission) in contrast to that of HIV-1 (15%–45% transmission).52,53,57-59 In studies that measured perinatal transmission of both viruses, the rate of HIV-1 transmission was 10- to 20-fold higher than that of HIV-2 (see Table 1).

**HIV-2-Related Disease and Differences in Disease Progression**

Early case reports described HIV-2-infected people with disease consistent with an AIDS diagnosis.60-62 The disease characteristics, including tuberculosis, chronic diarrhea, and *Candida* infections, were similar to diseases seen in HIV-1-associated AIDS in the same settings.62-64 Central nervous system involvement has also occasionally been described in HIV-2 AIDS cases.65,66 However, classical African AIDS comorbidities, such as tuberculosis, often have had only a weak epidemiological association with HIV-2, even in HIV-2-endemic areas.67-69

In Dakar, Senegal, our prospective studies conducted in a registered female sex worker cohort have provided the unique opportunity of measuring the infection and progression rates of both HIV-1 and HIV-2 infections.67,68,70,71 Importantly, these prospective studies have compared disease progression in individuals with known times of infection, and the cohort has now been observed for more than 22 years, representing one of the
alterations in T-cell subsets evaluated prospectively showed similar results, where immunosuppression was significantly slower to develop in HIV-2-infected people than in those infected by HIV-1 and could not be demonstrated in all subjects.68,73 Skin-test anergy to various antigens was also less pronounced in HIV-2 infection.68,73 Together, these studies of HIV-2 infection in populations in West Africa conducted in the 1990s demonstrated that the rate of immunosuppression and development of AIDS was significantly slower when compared with HIV-1 infection.

These distinct differences in pathogenicity provide a unique opportunity to identify viral and host immune mechanisms involved in a closely related and relevant virus system that is predicted to have a significantly slower course of progression. Evidence for a lower viral burden in HIV-2-infected individuals has been reported from both virus-isolation and PCR studies.76-82 The isolation rate of HIV-2 from peripheral blood mononuclear cells or plasma of asymptomatic HIV-2-infected individuals was lower than the isolation rate for HIV-1.80 At lower CD4 lymphocyte counts, virus isolation was equally efficient in both infections.

In our prospective study of HIV-2-infected individuals, we also identified individuals who fit a definition of long-term nonprogression and could determine a rate of this phenotype in the study population,68,71 also noted by others.72 Using a definition of long-term nonprogression of greater than or equal to eight years of infection in the absence of AIDS or related symptoms and stable CD4 (T4) lymphocyte counts greater than 500 cells/mm³, we found that 39 of 41 women (95%) could be classified as long-term nonprogressors.

Since it is well recognized that progression to AIDS correlates with clinical immunosuppression, studies to evaluate the level of immunocompromise with HIV-2 infection have been conducted to further define the clinical significance of HIV-2 infection. In cross-sectional studies, T4 lymphocyte counts and T4:T8 ratios appeared reduced in HIV-2-infected subjects, but less dramatically than in HIV-1-infected subjects.68,73-75 Similarly, alterations in T-cell subsets evaluated prospectively showed similar results, where immunosuppression was significantly slower to develop in HIV-2-infected people than in those infected by HIV-1 and could not be demonstrated in all subjects.68,73

*Non-nucleoside reverse transcriptase inhibitors

longest HIV natural-history studies in the literature. The Kaplan-Meier analysis of HIV-2-infected individuals indicates that 85% (95% CI, 50%-96%) remain AIDS-free after 8 years of HIV-2 infection.68 These differences in survival probabilities between HIV-2 and HIV-1 were also seen for Centers for Disease Control and Prevention (CDC) stage IV disease and CD4 lymphocyte counts below 400 cells/mm³ and below 200 cells/mm³, as outcomes.

In our prospective study of HIV-2-infected individuals, we also identified individuals who fit a definition of long-term nonprogression and could determine a rate of this phenotype in the study population,68,71 also noted by others.72 Using a definition of long-term nonprogression of greater than or equal to eight years of infection in the absence of AIDS or related symptoms and stable CD4 (T4) lymphocyte counts greater than 500 cells/mm³, we found that 39 of 41 women (95%) could be classified as long-term nonprogressors.

Since it is well recognized that progression to AIDS correlates with clinical immunosuppression, studies to evaluate the level of immunocompromise with HIV-2 infection have been conducted to further define the clinical significance of HIV-2 infection. In cross-sectional studies, T4 lymphocyte counts and T4:T8 ratios appeared reduced in HIV-2-infected subjects, but less dramatically than in HIV-1-infected subjects.68,73-75 Similarly,
reverse transcriptase–polymerase chain reaction to measure HIV-2 viral load and determined levels of plasma virus in the cohort of registered commercial sex workers in Dakar, Senegal.\textsuperscript{77} HIV-2 viral RNA was detectable in 56% of all samples tested; the median load was 141 copies/mL. Levels of HIV-2 viral RNA in the plasma were inversely related to CD4 cell counts. HIV-2 and HIV-1 viral loads were compared among newly infected women in the cohort; the median viral load was 30-fold lower in the HIV-2-infected women (\(P<.001\), Wilcoxon rank-sum test), irrespective of the length of time infected. This suggests that plasma viremia is linked to the differences in the pathogenicity of the two viruses.\textsuperscript{77} Similar findings have also been described in Gambia and Guinea Bissau.\textsuperscript{78,83}

Levels of virus in the plasma are closely related to the pathogenicity of HIV-1, and infection with HIV-2 leads to a significantly lower plasma viral load. To further identify the source of this difference, we measured both viral RNA and proviral DNA in matched samples from 34 HIV-2-infected individuals. The median level of HIV-2 RNA for the group was 189 copies/mL. Levels of HIV-2 RNA were below the limit of detection in nearly half the women, consistent with what we have previously reported in this population.\textsuperscript{76} Levels of HIV-2 proviral DNA were similar to those of HIV-1 but failed to correlate with levels of viral RNA. Thus, it appears that significant differences occur upon expression, release, and/or maintenance of virions in the bloodstream. Our laboratory has gone on to demonstrate that HIV-2 is able to establish a stable, integrated proviral infection in vivo, but that accumulation of viral mRNA is attenuated in HIV-2 infection, relative to HIV-1. The differences in viral mRNA are consistent with the differences in plasma viral loads between HIV-1 and HIV-2, and suggest that lower plasma viral loads, and possibly the attenuated pathogenesis of HIV-2, can be explained by lower rates of viral replication in vivo.\textsuperscript{44} Further comparative studies of both viral and host factors that may affect expression will be useful for understanding the differences between HIV-1 and HIV-2 pathogenesis.

Since slower disease course appears to be common in HIV-2 infection, we reasoned that certain subsets of the population would possess host characteristics that might predispose them to a more rapid disease course. We conducted a case-control study investigating possible associations between human leukocyte antigen (HLA) and the risk of disease progression in HIV-2.\textsuperscript{85} The HLA class I status was molecularly typed in female sex workers from the Dakar, Senegal, cohort; HLA B35 was associated with lack of p26 antibodies (\(P<.05\)) and higher risk of disease progression. The same association was found for the class I haplotypes B35-Cw4 and A23-Cw7 (\(P<.05\)), similar to the association with HIV-1.\textsuperscript{86} Our data show that certain HLA molecules are associated with risk of disease progression in HIV-2; some of the alleles and haplotypes involved in susceptibility to disease are similar for both HIV-1 and HIV-2. Therefore, certain genetic factors may be shared by HIV-1 and HIV-2 with respect to susceptibility to enhanced disease progression.

**HIV-2 Treatment**

It is generally assumed that drugs that have efficacy against HIV-1 will be effective against HIV-2. However, with the exception of a few in vitro analyses,\textsuperscript{87} most HIV-1 drugs have not been thoroughly tested for activity against HIV-2. In addition, experience with antiretrovirals (ARVs) has been largely confined to the developed world, where HIV-1 non-B subtypes and HIV-2 are rarer. Hence, it is still not clear that current ARV therapeutic regimes will be as efficacious given differences in virus subtype or type. Further, the natural history of HIV/AIDS in the developing world does differ from the disease in the developed world, where distinct...
endemic opportunistic infections, common infectious disease agents, and clinical standards of care may contribute to these differences. This suggests that certain aspects of HIV clinical management in developing-world settings will also require additional consideration. Antiretroviral therapy (ART) is directed at lowering in vivo virus replication. Clinical management and treatment decisions have been difficult in the absence of a commercially available HIV-2 plasma viral load assay.

We have had limited experience in the therapy of HIV-2 patients in the United States, where it appears that standard combination ART can readily reduce viral load levels below detection. To date, only case series and reports have evaluated the efficacy of HIV-1 ART regimens for the treatment of HIV-2 infection; clearly, clinical trials are needed in the future. Through a case series of 10 HIV-2-treated patients in the United States, Mullins et al reported that HIV-1 regimens have a reduced efficacy in the treatment of HIV-2 disease. From the few published studies, including our own, we are not able to adequately assess the clinical utility of the non-nucleoside reverse transcriptase inhibitor (NNRTI) class of antivirals as a treatment option for HIV-2, although in vitro data suggest that this class of drugs may be ineffective for treating HIV-2. Similar to our observations, it appears that HIV-2 differs from HIV-1 in the risk of disease progression at any given CD4 cell count and may therefore have different implications for the timing and management of ARV therapy.

The reverse transcriptase (RT) and protease genes from 12 HIV-2-infected individuals who had been treated with ARVs were examined for the presence of drug-resistance mutations. Four individuals carried virus genotypes with amino acid substitutions potentially associated with resistance to nucleoside analogues: two at codon 70 (K→R) and two at codon 184 (M→V); the latter two patients harbored a codon Q151M mutation, which has been associated with multidrug resistance in HIV-1. Substitutions associated with resistance to protease inhibitors at codon 46 were observed in all individuals. Moreover, minor resistance mutations, as well as new ones, were often seen in the protease gene. Thus, in limited studies, amino acid changes in the HIV-2 RT and protease genes, which could be associated with drug resistance, seem to occur at positions identical to those for HIV-1.

**HIV-1 SUBTYPES**

In the early 1990s, molecular techniques to sequence and classify HIV viruses became more available. These advances allowed for further characterization of HIV infections worldwide, with particular emphasis on Africa, which bears the highest rates of infection. It soon became apparent that genetic variation in HIV-1 led to distinct strains, subtypes, or clades. The genetic variability of HIV has been attributed to the lack of proofreading ability of the RT enzyme, the rapid turnover of virions, recombination of viruses, and selective immunologic pressures. Three distinct groups within HIV-1, M, N, and O, have been identified based on phylogenetic analysis of env and gag sequences from various geographic regions. Most HIV-1 sequences belong to group M (major). A divergent subset of viruses identified in Cameroon in 1994, which did not cluster with group M viruses, were classified as group O (outlier), and in 1998, another set of viruses, which did not cluster with group M or O viruses, were termed group N viruses. It is thought that the three groups were introduced by three independent SIVcpz transmissions into the human population in the early part of the 20th century. Interestingly, the earliest available HIV-1 isolate was sampled in the Democratic Republic of Congo in 1959, and molecular clock analyses estimate the timing of the most recent common
ancestor of HIV-1 group M to the 1930s\textsuperscript{100,101} and that of group O to the 1920s.\textsuperscript{102}

Prior to 1992, HIV-1 strains were classified based on their geographic origin, as European / North American versus African strains, because early phylogenetic analyses indicated that viruses from Europe and North America clustered separately and distinctively from viruses isolated in Africa.\textsuperscript{103-105} As more viruses from around the world were sequenced and analyzed, it became obvious that the original classification scheme was insufficient. Further analyses of env and gag gene sequences indicated the presence of multiple phylogenetic clusters, or clades, that were equidistant from one another.\textsuperscript{106} These clades were termed subtypes, which are defined as groups of viruses that closely resemble each other more than they do other subtypes.\textsuperscript{94,105,106} The viruses originally classified as European / North American were reclassified as subtype B, while the African viruses were
divided between subtypes A through F, excluding E. Subsequently, subtypes G, H, J, and K were also classified\(^\text{105}\) (Figure 1). To date, nine subtypes and 34 circulating recombinant forms (CRFs) have been described. In North America and Europe, the most prevalent form is the subtype B. However, in Africa, where the disease is the most prevalent, non-B subtypes predominate, with all nine subtypes and many CRFs described across the continent.

In addition to groups and subtypes, some group M subtypes have been further divided into subsubtypes.\(^\text{104}\) Based on full-length sequence data, subtype A has been subdivided into A1–A4,\(^\text{103,107,108}\) and subtype F into F1 and F2.\(^\text{109,110}\) It has also been suggested that the group of viruses designated as subtype K should actually have maintained the name F3, but for historical reasons it has been left as a separate subtype.\(^\text{104}\) Similarly, subtypes B and D should have been classified as related subsubtypes but have been maintained as separate subtypes as well.\(^\text{104,111}\)

At the nucleotide level, genetic distances between subtypes range from 15% to 22% in the gag gene, and from 20% to 30% in the env gene,\(^\text{103,104,112-114}\) while the genetic distances between subsubtypes range from 7% to 12% in the gag gene and 11% to 16% in the env gene.\(^\text{102-104,107,112}\)

Over the years, with the increasing use of full-length sequencing, it has become obvious that a number of intersubtype recombinants are also circulating in human populations. Recombination occurs when RT switches between two genomic templates during replication at an estimated rate of three recombination events per replication cycle.\(^\text{115}\) Recombination is usually preceded by dual infection of a cell with different viruses. The recombinants formed are of two varieties. They are either CRFs, which are widely spread in populations and usually have been found in at least three epidemiologically unlinked individuals, or unique recombinant forms (URFs), which do not attain epidemiological significance. CRFs are defined as recombinants that share an identical mosaic structure, indicating that they are descendants of the same recombinant event(s).\(^\text{104,111}\) As of February 2009, there were 43 CRFs listed in the Los Alamos HIV Sequence Database.\(^\text{115}\) There have also been reports of intergroup recombinants, composed of a mosaic of group M and group O viruses.\(^\text{116-118}\) Thus far, though dual infection with HIV-1 and HIV-2 has been shown in a number of studies, there has been no in vivo evidence of an HIV-1/HIV-2 recombinant.\(^\text{119,120}\)

**Geographic Distribution of HIV-1**

**Group M Subtypes**

Phylogenetic classification of HIV strains has assisted in tracking the diversity of the globally circulating strains. Subtypes C and A viruses account for most of the current HIV-1 infections worldwide, and they are followed by subtype B and the inter-subtype recombinants CRF01_AE and CRF02_AG. While subtype B viruses are primarily found in Europe, the Americas, and Australia, subtype C dominates in southern Africa and India\(^\text{94,103,121-123}\) (Figure 2). Subtype D viruses are predominantly found in central and eastern Africa, with a few cases sometimes appearing in southern and western Africa.\(^\text{20,103,124}\) Though a pure subtype E virus has never been found, it is part of the CRF01_AE recombinant form. CRF01_AE has been identified in Thailand, the Philippines, China, and central Africa. Subtype F has been found in central Africa, South America, and eastern Europe. Subtype G has been reported in western and eastern Africa as well as central Europe. Subtype H has been found only in central Africa. Subtype J was identified in Central America, and subtype K was found in the Democratic Republic of Congo and Cameroon. The recombinant virus CRF02_AG is the most prevalent virus in West Africa.\(^\text{20,94,122,125-132}\)

Despite the geographically specific distribution of some of the HIV-1 subtypes, we continue to see
From the ground up: establishing a framework for success

Factors. Primarily, it is believed that founder viruses were introduced into given populations, and once they adapted, they rapidly diversified. It has been hypothesized that the coexistence of different subtypes in a given population is determined by the biological characteristics of the subtype, in particular transmissibility and virulence, as well as by interactions and cross-infections between different risk groups. While the rate of HIV spread is not uniform across the globe, there appears to be an inverse correlation between the rate of disease spread and the variety of subtypes in a population. More specifically, in areas where the rate of spread has been relatively slow and stable, such as central Africa, we see a number of circulating subtypes in the population, as opposed to southern Africa, which has witnessed an explosive epidemic but has one predominant subtype. It has been speculated that the large variety of subtypes in central Africa

Figure 2. Worldwide distribution of major HIV-1 subtypes and HIV-2

It is difficult to interpret the variations seen in the distribution patterns of the various subtypes. As more than two decades have elapsed since the beginning of the HIV epidemic, the global patterns of spread are a result of a long period of evolution, which is nearly impossible to reconstruct. It seems likely that the geographic distribution of the different subtypes has been determined by a number of shifts in certain subtypes as the world becomes more of a global community. As immigration and travel increase, we have seen a shift in subtype distributions, and it has been estimated that anywhere from 25% to greater than 40% of the new infections in Europe are non-B variants of African and Asian origin. We are also witnessing an increasing number of non-B infections in the United States. For example, in a report on a well-studied military cohort, 6% of all new infections were due to non-B subtypes.

10 FROM THE GROUND UP: ESTABLISHING A FRAMEWORK FOR SUCCESS
has been due to the relatively low spread of HIV-1 in the population. Furthermore, it is believed that a number of subtypes can continue to coexist, potentially because of the low crossover between networks of risk groups.103

**HIV-1 Subtypes and Correlates of Disease and Pathogenesis**

In addition to the distinct epidemiologic patterns exhibited by various HIV-1 subtypes, differing biologic properties have been identified across some subtypes. There is evidence suggesting a relationship between subtype and modes of transmission. Studies in Cape Town,136 Finland,137 Thailand,138 Australia,139 and Chile140 found that most subtype B strains were associated with homosexual transmission while non-B strains were associated with heterosexual transmission. Similarly, in a study of U.S. military personnel, Brodine et al135 found that people infected with non-subtype B HIV were more likely to report heterosexual contact than those with subtype B infection.

Infection with certain subtypes has also been associated with increased risk of vertical transmission. A study conducted on mother-infant pairs in Tanzania revealed that mothers infected with HIV-1 subtype A, subtype C, and intersubtype recombinants were more likely to transmit to their infants than were mothers infected with subtype D.141 In an earlier related study, for perinatally transmitted C/D recombinant viruses, the V3 regions (env) were always from subtype C and never from subtype D, suggesting that viruses containing subtype D-V3 have a reduced fitness as compared to those with subtype C-V3.142 Conversely, a study conducted in Kenya indicated that women infected with viruses that contained some subtype D sequence were more likely to transmit than were women who had any other sequence combinations in the env and gag.143 Finally, a study of injecting drug users in Thailand found a significantly higher transmission probability associated with subtype E as compared to subtype B.144

Various studies have demonstrated significant differences between subtypes with regard to disease progression. We have described how Senegalese women infected with a non-A subtype were eight times more likely to develop AIDS than were those infected with subtype A.70 Studies from Uganda and Tanzania revealed that subjects with subtype A had a slower progression to disease than those with subtype D.145,146 Further research indicated that these differences might be explained by the fact that subtype D viruses are more likely than subtype A viruses to utilize the CXCR4 co-receptor for viral entry.147,148 Conversely, a study conducted in London, comparing HIV-1 disease in African immigrants and non-African Londoners, found no difference in progression by subtype. However, it should be noted that this study used a cross-sectional design and measured disease progression starting from when the HIV-1-infected person presented at the clinic.149

Clinical and immunological differences have also been found between subtypes. In Kenya, where subtypes A, C, and D were all co-circulating within the same population, it was found that high plasma RNA levels and low CD4 counts were significantly associated with subtype C infection.150

In a prospective study conducted at a methadone treatment clinic in Thailand, people infected with CRF01_AE were found to have higher viral loads in early infection than those infected with subtype B.151 However, this difference decreased over time, such that the viral loads were similar at 12, 18, and 24 months post-seroconversion.151 Similarly, a study in our laboratory indicated that women infected with CRF02_AG had a significantly higher viral load during the early stage of infection than did women not infected with CRF02_AG.152 Infection with multiple subtypes has also been associated with higher viral loads and
lower CD4 T-cell counts. Another study revealed that subjects infected with subtype D had lower average CD4 T-cell counts over the period of follow-up than did those infected with subtype A. Conversely, a study conducted in Thailand found no major differences with regard to the degree of immunosuppression or rates of opportunistic infections between people infected with subtype B' (Thai B) or CRF01_AE. However, it must be noted that this study was cross-sectional and that the analyses of lymphocyte counts did not take into account the time since seroconversion or the disease stage for any of the subjects assessed when comparing across the groups.

A few recent studies have identified structural and functional differences across subtypes. An in vitro study showed that viruses expressing a subtype C Vpu protein replicate with a lower efficiency than those expressing a subtype B Vpu; furthermore, when these viruses containing subtype C Vpu were injected into macaques, there was a more gradual CD4 T-cell decline as compared to macaques injected with viruses containing subtype B Vpus. Subtype B viruses also were shown to have longer gag proteins than non-subtype-B viruses; this variation could potentially affect protein structure and function. Preliminary data evaluating nef protein sequences revealed that insertions and deletions found in subtype C nef, which are not found in subtype B, might be associated with a slower disease progression. Finally, subtypes have been shown to differ in their propensity to recombine with other subtypes or CRFs; a recent in vitro study indicated that subtype C viruses were more likely than subtype B viruses to recombine with CRF01_AE.

Variation in subtype has also been associated with different levels of interaction with HIV-2. Sarr et al showed that the in vivo interaction between HIV-1 and HIV-2 was influenced by HIV-1 subtype. They found that the prevalence of CRF02_AG viruses was significantly higher in dually infected individuals compared with women who were singly infected with HIV-1.

A number of recent studies looking at resistance mutations have revealed differences in mutation patterns across subtypes. A study in Brazil suggested that subtype C viruses have a lower rate of accumulation of mutations conferring resistance to ARV than do subtype B viruses. ART-experienced patients infected with subtype A had a lower prevalence of K65R and Y181C than those with subtypes B or C. M89I/V was significantly more frequently observed in protease-inhibitor-treated patients with subtypes C, F, or G infection than in those with subtype B. Some studies found that HIV-1 subtype can influence selection and fading of HIV-1 variants with specific drug-resistance mutations after antiretroviral drug exposure. Following administration of single-dose nevirapine (sdNVP) for prevention of mother-to-child transmission (PMTCT), NVP-resistance mutations were higher in subtype-D-infected patients than in those with subtype A. The differences could be explained by the finding that Y181C faded from detection at a greater rate in women with subtype A, and K103N accumulated at a greater rate in women with subtype D. Additional studies showed that NVP resistance is highest in subtype C patients, followed by those with D and finally those with subtype A.

Some cross-sectional studies have failed to demonstrate biological or clinical differences in genetically diverse viral strains. A recent study found no difference in the rate of CD4 decline, clinical progression, or plasma HIV-1 RNA levels between individuals infected with subtypes A, B, C, or D. Laurent et al found no difference in survival, clinical disease progression, or CD4 decline between those infected with CRF02_AG and those infected with other strains of the virus. In addition, in a study comparing differences between subtypes...
A and D in mother-to-child transmission, subtype did not appear to influence infant survival.167

Impact of HIV-1 Subtypes on Vaccine Development

One of the major challenges to the development of an effective HIV vaccine is the genetic diversity of the virus. As a result, the role of HIV-1 subtype variation must be seriously considered—particularly given the geographic distribution of HIV-1 viruses, with Africa and Asia harboring the largest proportion of HIV-1 variants or subtypes. To date, it is not yet known the degree to which HIV-1 subtypes, subsubtypes, and circulating recombinant forms may be important in the design of an effective HIV vaccine.95

Whether or not a candidate vaccine against HIV-1 should be based on the dominant subtypes in a given region is unclear and the subject of much speculation and debate. In order to appropriately address the issue, one must consider the relationship between the HIV-1 genetic subtypes and immune responses. Since the most effective neutralizing antibodies appear to be effective across genetic subtypes, it has been argued that a vaccine targeting the humoral immune response focused on genetic subtypes would not be necessary; some support the approach of targeting more conserved regions of the genome, and that is likely to yield cross-protective immunity. Evaluation of cellular immunity by subtype has also indicated that cross-recognition across subtypes may be possible, at least in natural infection.168,169 As Moore et al105 point out, given that subtype designations were not made based on the antigenic or immunogenic properties of the virus and they do not correspond to neutralization serotypes, it might not make sense to be concerned with generating a subtype-specific vaccine, rather one that is broadly cross-reactive. Furthermore, the issue of superinfection and recombination begs the question of whether or not a vaccine generated against a single subtype will be cross-protective against other subtypes of virus.170

Nonetheless, there are many researchers who are still interested in generating clade-appropriate vaccines for given regions. The belief is that a subtype-specific vaccine candidate might increase the number of potentially cross-reactive epitopes by augmenting the level of similarity between the vaccine and the population. For those designing subtype-specific vaccines, there are two major approaches: isolate-based, or consensus- or ancestral-sequence-based vaccines.171 The first approach involves the selection of an isolate from the geographic region to which the vaccine is directed, while the second approach requires the construction of either a consensus or ancestral sequence using all available sequence data and an evolutionary model.171 When considering the possibility of using an isolate-based vaccine, the question arises as to where the representative isolate should be chosen from. Given the great diversity within subtypes and the fact that the geographic restrictions of viruses are slowly disappearing, this is a difficult choice. One solution is to use a polyvalent vaccine containing isolates as well as a group M consensus sequence.171

Overall, even though many recommend against generating subtype-specific vaccines, it is important to test the vaccines for all the subtypes to make sure that they are equally effective, as it has been found that, when used individually, the broadly neutralizing antibodies 2F5, 2G12, and IgG1b12 were not effective against a subtype C primary isolate but were effective when used in combination.172

CONCLUSION

In summary, HIV’s propensity for genetic diversification has resulted in two closely related HIV types, HIV-1 and HIV-2. These viruses have a distinct geographic distribution, with HIV-2 predominating in West Africa. Current epidemiologic trends suggest that HIV-2 is unlikely to result in a global
pandemic like HIV-1 and may in fact be decreasing in endemic regions. Major differences in the biologic properties between HIV-1 and HIV-2 suggest a more ancestral history to HIV-2 with adaptation to the human host and relative attenuation. This has resulted in lowered transmission potential and decreased pathogenicity. The diversification of HIV-1 appears to be more recent and less well understood. HIV-1 subtypes, subsubtypes, and recombinant forms demonstrate a unique geographic distribution, even within the African continent. Current studies suggest that the epidemiology of these variants is dynamic, particularly within Africa. In the future, it will be important to molecularly characterize HIV subtypes in order to accurately map the molecular epidemiologic timeline. This may indicate important differences in the transmission and pathogenic properties of HIV subtypes and determine their impact on HIV infection and potential immune correlates. Finally, it seems clear that the quest for an effective HIV vaccine will need to determine the impact of HIV diversity on the ability to provide protection. Further research—particularly in Africa, where these diverse HIV types, subtypes, and recombinant forms exist—will be critical to our ability to integrate this information in effective therapeutic and prophylactic interventions.

During the course of viral infections, many viruses are not eradicated from the human host but are rather held in a state of containment by the host immune response, leading to a persistence or latency of the viral infection. A consequence of this viral persistence is the likelihood of reactivation of the infection if immune control ceases. This reactivation may occur during a state of immunodeficiency, perhaps accompanied by either a symptomatic or an asymptomatic viral reactivation. Prime examples of this phenomenon occur among viruses belonging to the Herpesviridae family, such as herpes simplex virus (HSV), cytomegalovirus (CMV), varicella-zoster virus (VZV), or Epstein-Barr virus (EBV). Immunodeficiency allows viral escape to take place, and varying forms and severity of reactivation disease may occur. These latent/persistent viruses are held in check by various components of the immune system.

OVERVIEW OF THE IMMUNE SYSTEM
There are two basic components of the immune system: the innate system and the adaptive system.

Innate Immune System
A wide range of innate immune mechanisms operate as a first line of defense upon exposure to infection. The physical barriers to infection include skin, mucous secretions, ciliary action, lachrymal tears, gastric acid, and the antagonistic effect of normal microbial flora. If penetration occurs, bacteria are destroyed by soluble factors, such as lysosomal enzymes, and through ingestion by phagocytic cells. The main phagocytic cells are polymorphonuclear leucocytes and macrophages. Once engulfed by phagocytic cells, these organisms are destroyed by a number of microbicidal mechanisms, including reactive oxygen intermediates or the synthesis of nitric oxide, which is released within cytoplasmic granules. The complement system, which is a multicomponent system, is triggered to attract phagocytic cells. Following activation of the complement system, with the accompanying activation and attraction of phagocytic cells and neutrophils, an inflammatory response occurs. There is also an elaboration of other acute phase proteins, such as C-reactive and mannose-binding proteins, which augment the inflammatory response.
Extracellular killing of virally infected cells can be carried out by natural killer (NK) cells. NK cells, an important component of the innate immune system, participate in early responses against infected or transformed cells either through the production of cytokines or by direct cytotoxicity. These responses are mediated through interactions involving killer cell immunoglobulin-like receptors (KIRs), which are found on the cell’s surface. Various KIR isotypes promote stimulation of NK cell activity, whereas others cause inhibition of activity. KIR isotypes function in close association with human leukocyte antigen (HLA) molecules. The KIR allele KIR 3DS1, in the presence of HLA-B BW4-80ILE, has been shown to delay HIV disease progression. Lysis by NK cells can also take place against cells recognized by host antibodies through binding of immunoglobulin to fragment constant (Fc) receptors on the NK cells.

Toll-like receptors (TLRs) play a key role in the response to microbial infections. TLRs recognize structurally conserved molecules derived from microbes and activate an immune response once these molecules have breached physical barriers, such as skin or intestinal tract mucosa. TLRs are believed to be a crucial component of the innate immune system and appear to be one of the most ancient, conserved components of the immune system. TLRs, which are a type of pattern-recognition receptor, recognize molecules that are broadly shared by pathogens but that are distinguishable from host molecules, collectively referred to as pathogen-associated molecular patterns (PAMPs).

During acute primary HIV infection, there is an acute depletion of CD4 cells in the intestinal mucosa, leading to compromise in the integrity of mucosal epithelium. A consequence of this is the translocation of microbial products from the lumen. These products include lipopolysaccharide (LPS), peptidoglycan, and bacterial 16sDNA, which all interact with TLRs and have the capacity to cause intense immune activation of a broad range of T cells. Upon engagement with the TLR, the T cells enter the cell cycle but fail to complete division and instead die by apoptosis. Further evidence of the role of the TLRs’ response to microbial products suggests that there is a direct correlation between LPS in plasma and the individual’s state of immune activation. The highest levels of LPS were found in progressive disease, whereas the lowest levels were found in long-term nonprogressors. Levels of bacterial products were also correlated with the state of activation of T cells and CD4 lymphocyte levels.

Cellular Factors

The recently identified protein called APOBEC3G has both an antiviral and an antiretroviral effect. This protein is from the APOBEC family of cytidine deaminases, which hypermutate retroviral genomes and render them unstable. These proteins are expressed in the natural target cells for HIV infection, namely CD4 lymphocytes and macrophages. When the virus infects these cells, APOBEC3G is packaged into the viral particle. When the virus subsequently infects a new cell, the APOBEC3G within the viral particle hypermutates the nascent viral complementary DNA (cDNA), which is then degraded. The vif gene product of HIV attempts to overcome this innate antiviral response by binding to the protein and overcoming its effect. TRIM5alpha is another cellular factor shown to have activity against HIV-1. This cellular protein interacts with the viral capsid and interferes with the uncoating process through which viral RNA is released into the cytoplasm of an acutely infected cell.

A feature of the wide range of innate immune responses is that they are not amplified by repeated exposures to infection (in contradistinction to the adaptive system). Recovery from viral infections can be assisted by interferons.
THE CLINICAL FEATURES OF ACUTE primary infection develop days to weeks after acquisition of HIV infection. The manifestations are protean and include a nonspecific influenza-like illness, infectious mononucleosis-like illness, or an acute neurological presentation, often with acute aseptic meningitis. It is important to take a good clinical history, as symptomatic primary infection occurs in the majority of cases. Generalized lymphadenopathy may be present, which more commonly involves the cervical nodes. In sub-Saharan Africa, clinical diagnosis may be made more difficult by the high burden of acute febrile illnesses.

**Diagnosis of Acute Primary Infection**
Routine laboratory testing may provide clues to aid in the diagnosis of acute primary infection. Hematological abnormalities are frequently noted, including thrombocytopenia, anemia, leucopenia, lymphopenia, and monocytosis, and atypical lymphocytes may be present on a blood film. CD4 counts are usually decreased, and there is a reversal of the CD4:CD8 ratio.

Tools used to detect primary infection in the absence of seroconversion include p24 antigen assays and nucleic acid testing. Assays for p24 antigen are widely available and relatively inexpensive. However, the sensitivity of this assay is often suboptimal due to antibody that has formed a complex with the antigen. The assay’s sensitivity can be enhanced by using an immune complex dissociating step before performing the assay.

Where resources are available, the test of choice is the polymerase chain reaction (PCR) test for HIV-1 RNA. During acute infection, the HIV RNA levels are typically greater than 10,000 copies/mL of plasma. Levels lower than 10,000 copies/mL warrant further investigation.

**Adaptive Immune System**
The primary cells of the adaptive immune system are lymphocytes, which are derived from pluripotent cells in the bone marrow. The lymphocytes undergo serial proliferation and differentiation, ultimately leading to the development of a cellular and humoral immune response (Figure 1).

**Cellular Response**
Bone marrow–derived lymphocytes actively divide in the thymic cortex and then migrate to the medulla, where they are induced to differentiate into cells that will eventually participate in cellular immune responses. The thymus gland is very active in infants and is responsible for the selection of T cells in the body that will provide protection throughout life. During a person’s lifetime, the thymus gland atrophies and becomes smaller; until recently, it was thought that the gland became inactive after the third decade of life. Recent evidence suggests, however, that the gland retains activity throughout a person’s life, but that the thymic reserve declines with age. These emigrant naive T cells migrate to the secondary lymphoid tissues, such as the inner cortex of the lymph nodes, the periarticular sheaths in the lymph nodes, and the Peyer’s patches in the gut, tonsils, and appendix. Once at these sites, the thymic-dependent T lymphocytes become immunologically competent.
T cells only recognize antigen when it is on the surface of a body cell. Accordingly, the T-cell surface receptors recognize antigen when it is presented in conjunction with another surface marker belonging to a group of molecules known as the major histocompatibility complex (MHC). When this occurs, a naive T cell is introduced to an antigen and becomes “primed” and activated as an effector cell. There is a constant movement of naive, effector, and memory cells from the blood circulation to the lymphatic circulation and lymph nodes. Antigen-primed T cells migrate to tissues where HIV replication occurs; in these tissues, clonal expansion and recruitment of other effector cells takes place, leading to hyperplasia of the tissue, which manifests as lymphadenopathy, a condition often seen in early phases of HIV infection.
Cytotoxic T lymphocytes (CTLs) bear the CD8 molecule and are a major immunological mechanism in the control of viremia. They inhibit viral replication in at least two distinct ways. In the first instance, direct killing of infected cells takes place. When a virus invades a cell, a proteolytic degradation of viral proteins takes place. These proteins are then transported into the endoplasmic reticulum, where they form a complex with a developing MHC class-1 molecule and are transported to the cell surface. The presence of the viral protein (usually 8–10 amino acids in length) within the protein-binding cleft of the class-1 molecule acts as an immunological signal to CTLs. This event activates the CTL to kill the infected cell through a direct recognition mediated by the T-cell receptor (TCR) on the CTL. This cell killing is carried out through the production of granzymes and perforins by the CTL. Although most cytolytic activity is mediated through this route, CD8 cells expressing Fas ligand can also bind to Fas (CD95) on the surface of target cells, thereby inducing apoptotic cell death. At the same time, activation of the CTL leads to the release of soluble antiviral factors, which inhibit progeny viruses from entering target cells. These antiviral factors include the beta chemokines RANTES (regulated on activation normal T cell expressed and secreted), MIP1α (macrophage inflammatory protein 1α), and MIP1β. These chemokines prevent HIV from entering cells by competing for binding to certain co-receptors and promoting internalization of the HIV co-receptor. RANTES, MIP1α, and MIP1β are active against macrophage-tropic chemokine receptor 5 (CCR5, or R5) viruses; other soluble factors are active against CXC chemokine receptor 4 (CXCR4, or R4) viruses.

Recent studies have reported additional antiviral factors that are produced by CD8 cells but that are clearly not chemokines. A group of defensins produced by neutrophils and CD8 cells have a similar action. This compound is probably one constituent of soluble antiviral factors loosely termed CD8 antiviral factor (CAF). These factors act by inhibiting viral transcription and appear to have an action that is distinguishable from chemokine- or defensin-mediated viral suppression. CD8-mediated responses may be related to progression of HIV disease and disease outcomes.

All T lymphocytes bear the CD3 molecule and the T-cell receptor. The major T-cell subset bears the CD4 molecule, and these T cells are responsible for coordinating and helping the immune response—hence, the name T-helper cells. They promote CD8 cell activity and support B cells in the production of antibodies.

In addition to CTLs, the cellular immune response also relies on virus-specific T-helper cells. T-helper cells bear the CD4 molecule, and these T cells are responsible for coordinating and helping the immune response. The T-helper cells become activated and drive immunological signals to other categories of immune cells by direct cell-to-cell interactions and by the release of soluble factors. In this instance, the viral peptides that serve as targets for the T-helper response tend to be larger and are often 12–15 amino acids in length. A hallmark of progressive HIV infection is the lack of strong HIV-specific T-helper cell responses, which are lost early in the infection; this loss often occurs during acute primary infection. There are interesting clinical correlates of this phenomenon. In patients who have strong T-helper responses, viral suppression is good. This is also seen in so-called elite controllers, where T-helper responses are optimal.
antigen receptors and as identification markers. Upon stimulation, these cells undergo blast transformation, proliferation, and differentiation, eventually becoming plasma cells that produce antibody. The majority of antibodies in HIV infection are nonneutralizing and are often directed against virion debris rather than against conformational epitopes on intact virions. Neutralizing antibodies are directed against a number of different epitopes, including antibodies that prevent entry of virus into cells (directed against the V3 loop) and into CD4 binding (CD4-binding-site antibodies). Some antibodies are directed against linear portions of the viral envelope, whereas others are directed against conformational structures.

Some potent neutralizing antibodies do not prevent binding of glycoprotein 120 (gp120) to CD4; instead, they interact with the viral–receptor complex, thus preventing the necessary conformational change that allows entry to be mediated by gp41. Neutralizing antibodies as a means of immune control have been problematic in that they tend to be weak and lack broad cross-reactivity. The viral envelope displays considerable adaptability, with the capacity to revise its glycosylation sites, resulting in a changed three-dimensional configuration that allows it to escape antibody-mediated neutralization. Lack of capacity to neutralize new strains arising within an individual results in an expansion of the viral “quasi species.” The relationship of autologous neutralizing antibody responses to disease progression has been studied. Studies comparing the strength and breadth of neutralizing antibodies in long-term nonprogressors and rapid progressors (see definitions later in this chapter) showed that responses in “controllers” was significantly greater than responses in “progressors.”

As with the cellular immune responses, the humoral responses are often disregulated and are characterized by paradoxical hyperactivation and hyporesponsiveness. Hyperactivation is reflected by polyclonal hyperglobulinemia, only a portion of which is directed against HIV antigens. Other features of the hyperactivation include bone marrow plasmacytosis, heightened expression of activation molecules on B lymphocytes, and the presence of autoreactive antibodies in plasma. The humoral hyporesponsiveness is manifested by a decrease in protective antibody responses to antigens and after immunization with protein or polysaccharide vaccines.

Other Important Components of the Immune System

**Macrophages**

Infection of monocytes/macrophages occurs via the CD4 receptor, which is expressed on the cell surface; however, this infection is in smaller numbers as compared with CD4 lymphocytes. Because macrophages do not undergo lysis, these cells become significant reservoirs of HIV. Monocyte migration from the blood to tissues takes place continuously, facilitating the transport of the virus to various tissues and anatomical compartments. Both monocytes and macrophages are antigen-presenting cells that stimulate T- and B-lymphocyte responses; they are also primary effector cells. They both have an extensive array of antimicrobial, antifungal, chemotactic, and secretory functions, including the production of proinflammatory cytokines. Although many of these functions are preserved in HIV infection, many others are not. One of the most important functional impairments relates to the decreased killing of mycobacteria, which is significant due to the high burden of mycobacterial disease in developing countries, where the majority of HIV infections occur.

**Dendritic Cells**

Dendritic cells (DCs) are an important group of antigen-presenting cells that are derived in the bone marrow from precursor CD34 stem cells and
that act as a primer of the immune response. DCs, which are found in lymphoid tissue and in non-lymphoid tissues (e.g., lungs, skin, and brain), trap antigens and migrate to lymphoid tissue, where the antigens are presented to immunocompetent cells. There is also a concentration of DCs within lymph nodes; these DCs form part of the follicular dendritic network. Over the course of HIV disease, there is a loss of the follicular dendritic network, presumably due to a loss of interactive signals with immunocompetent cells and to a disturbance in the tissue's cytokine milieu.36

DCs are thought to play an important role in the early events of HIV infection. The major pathway of viral transmission is by cell-associated virus, which is taken up by interdigitating dendritic cells (Langerhans cells) situated in the cervical, vaginal, and rectal mucosa. These cells are characterized by the expression of CD1a and the presence of Birbeck granules. Virus has been shown to be carried on dendritic cells by way of DC-SIGN (dendritic cell-specific ICAM-grabbing non-integrin) to the regional lymph nodes, where a bridgehead of infection is established. Two populations of DCs can be identified in blood: myeloid dendritic cells (characterized by expression of CD11c) and plasmacytoid dendritic cells (CD123). Circulating numbers of these cells tend to be diminished in HIV infection, and this may occur early in primary infection.37,38

The Role of Cytokines
CD4 cells communicate with other cellular components of the immune system by either cell contact or the elaboration of soluble factors known as cytokines. There are a number of different cytokines, each having different and distinct actions. A bipolar Th1/Th2 concept was originally described in the mouse model, in which there was a division of CD4 cells into Th1 and Th2 cells based on the cytokine production from the respective cells.39,40 Due to the enormous complexities of the human immune response, this model is not directly applicable to humans. However, relevant features can provide some insights into immunopathogenesis during the course of HIV infection. Th1 cells secrete cytokines that will drive a cell-mediated immunity effected predominantly by CD8 cells. Examples of these cytokines are IL-1, IL-2, IL-6, IL-12, IL-15, tumor necrosis factor alpha (TNF-α), and interferon-γ. A Th2 response drives a humoral immune response and will stimulate B cells. Th2 cytokines include IL-4, IL-5, and IL-10. Th1 and Th2 cells are derived from a precursor Th0 cell that is thought to be a naive cell capable of secreting a broad range of cytokines. It is postulated that the differentiation into a Th1 or Th2 response is a function of the type of antigen initially encountered and the immunological environment predominating in the tissue at that time (Figure 2). There is a cross-regulation between these distinct responses, as well as a synergism in the differing modes of action. During HIV disease progression, CD4 cell loss leads to a progressive decline in the Th1 responses and therefore to a progressive decline in cell-mediated immunity, with a switch to Th2-type immunity in late-stage disease.

There is also a group of CD4 cells, classified as T-regulatory (Treg) cells, that serve a regulatory function. These cells, which bear the CD25 marker, are able to inhibit both Th1 and Th2 responses.41 The Treg cells express cytokine IL-10 and transforming growth factor beta (TGFβ). Some contrasting effects have been attributed to Treg cells, including impairment of HIV-specific responses on the one hand and suppression of immune activation on the other.42

Recent research has demonstrated the possible importance of Th17 cells, which elaborate a cytokine IL-17. IL-17 is important in host defense against extracellular pathogens, such as bacteria and fungi. Th17 cells are profoundly depleted in
levels of immune activation have been shown to be a feature in HIV-negative subjects in Africa when compared with their European counterparts, suggesting that environmental factors may be responsible for this observed difference. Some investigators speculate that hyperimmune activation demonstrated in Africans may be a contributing factor in the pathogenesis of AIDS in Africa. This immune activation has the potential to create a situation where HIV can be more readily acquired and, if acquired, can lead to a more rapid progression of disease.

The gut mucosa of HIV-infected individuals and in pathogenic models of simian immunodeficiency virus (SIV) infection. With the loss of Th17 cells, bacterial commensals within the gut lumen may gain access to deeper tissues and contribute to the events involving the gut-associated lumen tissue (GALT) in primary infection, leading to immune activation and CD4 cell loss. The proinflammatory cytokines, particularly TNF-α, can upregulate HIV replication and drive high viral loads, as was seen in a cohort of HIV-infected African patients during and after treatment for tuberculosis. Abnormal

**NATURAL HISTORY OF HIV INFECTION**

Figure 3 outlines the events occurring in the typical course of HIV infection. The sections that follow provide a detailed description of immunological events occurring at points A through E.

**Point A**

Point A represents the time of acquisition of HIV infection. At this time, the immune system's status is normal (as represented by the CD4 count, which in adult subjects lies between 800 and 1200 cells/mm³). This is followed by a rapid burst of viral replication, during which very high levels of virus are often recorded. The replication of virus takes place in CD4 lymphocytes, leading to a loss of CD4 cells. Although destruction of CD4 cells occurs throughout the body, it is particularly profound in the gut’s mucosa-associated lymphoid tissue.

**Point B**

Point B represents the curtailment of the burst of HIV replication. The control is initially brought about by a cellular immune response, predominantly in the form of CD8 cytotoxic lymphocytes.⁴⁶,⁴⁷ Animal models have also demonstrated the importance of CD8 T-cell responses in the control of viremia during primary infection with SIV.⁴⁸ Although antibodies are detected at this time, they do not contribute meaningfully to the curtailment of viral replication, because they are nonneutralizing. Antibodies are, however, useful in the clinical context in that they can be detected by various test systems (usually serological) for identifying HIV infection. The interval between point A and point B is referred to as the window period, during which the patient is antibody negative even though viral replication can be detected. The appearance of the immune response at point B is often accompanied by
a clinical illness, which can take various forms and is known as the seroconversion illness. This illness often resembles an acute mononucleosis syndrome, similar to that seen in acute EBV infection. In both HIV and EBV infection, the clinical syndrome is caused by the immune response to the respective virus. Viral levels are suppressed, and, depending on the quantity and quality of the immune response, a level of virus in the body is reached that is unique to each individual. This “viral set point” has prognostic significance, in that patients with lower viral set points enjoy a survival advantage.

**Point C**

Although there is some recovery in CD4 levels in the peripheral blood at point C, premorbid levels are not regained. The maturation of the immune response may take several months, and it is only then that an effective viral set point is reached. The patient then enters the period of clinical latency (point D).

**Point D**

Point D may last for a number of years. During this period, the patient is usually asymptomatic or at most mildly symptomatic. Viral levels (i.e., viral load) remain remarkably constant, with occasional periodic “viral blips.” These blips are due to upregulation of viral replication, often brought about by the immune activation surrounding an intercurrent infection or immunization. When the immune activation ceases, the viral levels fall back to previous set-point levels. During this clinical latency, however, there is a progressive and gradual loss of CD4 cells brought about by various pathogenetic mechanisms.

With the decrease in CD4-cell functionality, particularly in regard to the help they offer CD8 cells, viral escape from the immune system takes place, accompanied by increasing viral levels and expansion of the viral quasi species. Numerous studies have shown that CTL responses decline with disease progression; this decline is probably related to the number and functionality of virus-specific T-helper cells.

The architecture of lymphoid tissue is also altered over time, resulting in progressive loss of the follicular dendritic cells (FDCs). During the early phases of disease, lymph nodes are hyperplastic, with trapping of virus within the FDC network and continual presentation of antigens to the immune system. With the disintegration of the lymphoid tissue, however, the virus is no longer trapped, resulting in a spillover of virus into the peripheral blood. This spillover contributes to the high blood levels of virus seen in the later stages of HIV disease.

**Point E**

When the amount of CD4 cells reaches critically low levels (usually less than 200 cells/mm³), symptomatic disease and other opportunistic events are likely to occur. At this time, various virological and immunological events have taken place. With the loss of immune control comes an expansion of the viral quasi species and a change in the tropism of the virus from a macrophage-tropic virus, which utilizes the CCR5 molecule for viral entry (R5 virus), to a lymphocyte-tropic virus, which utilizes the CXCR4 molecule as a co-receptor (R4 virus). Monitoring of CD4 counts and viral load is important at all stages of infection, as it is used to help clinicians determine when to commence preventive chemotherapy for opportunistic infections and when to commence antiretroviral therapy (ART). Both of these therapies attempt to halt and, to an extent, reverse the immunological damage that has taken place. In recent years, the timing of ART initiation has undergone modifications in an attempt to strike a balance between protection of the immune system and prevention of the long-term effects of ART.
During the course of HIV infection, there is a switch from R5 to R4 viruses (Figure 4). Studies have shown that subtype-C viruses almost exclusively utilize CCR5 for viral entry and that individuals who are homozygous for a deletion of the gene coding for CCR5 (CCR5Δ32) are resistant to HIV infection. The mutant CCR5 allele is most commonly detected in Caucasian populations. Individuals who are heterozygous for the CCR5 deletion have a slower progression of disease. To date, the mutant allele has not been detected in African or Asian populations. There have been conflicting reports on the influence of the 64I allele of CCR2 on disease progression, with some studies showing delayed progression and others showing no influence of the mutant allele. Notably, among a cohort of sex workers in Kenya who showed resistance despite repeated high-risk exposures to HIV-1, resistance was not related to any of the above polymorphisms in the chemokine receptors.

**Chemokines**

Chemokines are soluble proteins that attract white blood cells to sites of infection or inflammation in the body. They are expressed in a wide range of cell types and tissues in the body and are classified into two subfamilies: CXC or α-chemokines and CC or β-chemokines. HIV utilizes the chemokine receptors on CD4 cells as a co-receptor, an interaction necessary for viral entry. Macrophage-tropic HIV-1 viruses are nonsyncitium inducing (NSI) in culture systems and utilize the CCR5 receptor for viral entry (R5 viruses). Almost all new infections are due to macrophage-tropic viruses. The β-chemokines MIP1α, MIP1β, and RANTES are the normal physiological ligands for CCR5. These agents prevent entry of HIV into cells. T-cell-tropic viruses, which are syncitium inducing (SI), utilize CXCR4 for viral entry (R4 viruses). The normal physiological ligand for CXCR4 is stromal-derived factor 1 (SDF1).
MECHANISMS OF CD4 CELL LOSS
A hallmark of HIV disease is the functional impairment of CD4 lymphocytes, as well as their loss in lymphoid tissue. A sequential loss of immune responsiveness to recall antigens, followed by alloantigens and then mitogens, has been described.\(^\text{36}\) The depletion of CD4 cells appears to result from factors other than the direct cytopathic effect of HIV itself. Destruction of CD4 cells by various mechanisms, diminished production of CD4 cells, and the sequestration of CD4 cells in lymphoid tissue all appear to contribute to the decrease in circulating CD4 cells. CD4 T cells have a key role in mediating immune responses through the production of immunomodulatory cytokines; the loss of these cells and the failure of the remaining cells to function adequately lead to a critical impairment of immune responses.

Diminished Production
In HIV disease, the output of lymphocytes from the bone marrow is impaired. This impairment may arise from diminished functionality of progenitor CD34 cells, which appear to be susceptible to HIV infection,\(^\text{61,62}\) or from the replacement of bone marrow tissue due to mycobacterial infection or lymphoma in more advanced disease. T lymphocytes undergo maturation and differentiation in the thymus gland, where T cells with very high avidity for host HLAs that bind endogenous peptides are deleted, thus reducing the risk of autoimmune reactivity. Also eliminated are T cells with a low avidity for the host HLAs, thus ensuring that the remaining cells are potentially capable of recognizing host HLAs that bind foreign peptides. The population of antigen-naive T lymphocytes that emerges contains a diverse distribution of T-cell receptors capable of recognizing a broad array of peptide antigens. Although thymic activity is greatest during early development and childhood, there is evidence that thymic function still occurs in adults.\(^\text{8}\) There is also evidence that HIV can infect thymic stromal cells and that R4 viruses can infect thymocytes, thus interfering with thymic function.\(^\text{63}\)

The role of the thymus in HIV disease is complex. Thymus size is often preserved in HIV-infected adults and can also be evident in older subjects;\(^\text{64,65}\) there is also indication that thymic output is maintained in HIV-uninfected people.\(^\text{66}\) Other evidence indicates that thymic size decreases after viral suppression with ART, suggesting that thymic
epitope can abolish CTL recognition. Failing CTL function is an important correlate of HIV disease progression. A study of HIV-positive mothers who transmitted virus to their children showed that CTL escape played an important role in the transmission of virus. HIV-positive children who expressed HLA B27, an allele usually associated with viral control in adults, failed to have adequate viral control and had higher viral loads. Investigation revealed that mothers who expressed HLA B27 also transmitted a CTL escape variant to their children, such that the dominant B27-restricted Gag epitope could not be targeted. In contrast, children who inherited HLA B27 from their fathers and received virus from their mothers (who had not been under B27-restricted selection pressure) were able to mount a vigorous CTL response and achieve better viral control.

Apart from the viral escape mutation mechanism that interferes with the cytotoxic activity of CD8 cells, it has been shown that CD8 cells may become dysfunctional. This dysfunction may be due to reduced lytic activity, poor proliferation in vitro, or decreased expression of signaling molecules that mediate T-cell receptor activation.

Neutralizing Antibodies
There is a rapid evolution of immune escape directed against the predominant viruses circulating in the blood. Escape occurs mainly through mutations in glycosylation sites in the envelope protein. A new generation of antibodies then evolves to deal with this “new” mutant virus, and the process is repeated. Unfortunately, these responses are type specific, and there is limited cross-reactivity.

Viral Diversity
HIV is a retrovirus with an inherent capacity to develop viral mutations because of an error-prone reverse transcriptase enzyme and the lack of a corrective proof-reading mechanism. This capacity
is further fueled by high levels of viral replication and the effect of the immune system's selection pressure. Even a single mutation in a defined CTL epitope is sufficient to impair CTL recognition.81

Establishment of a Viral Reservoir

Most T cells exist in the resting state, with approximately half being naive cells that have not yet responded to an antigen. The remainder of the resting T-cell population consists of memory T cells, which have encountered antigen and have been programmed to react to that specific antigen in the future. When these memory cells encounter the antigen a second time, they become activated, undergo blast transformation, and carry out that cell's specific immunological function. After the immunological event, a small number of these cells revert back to the resting memory cell state. HIV preferentially replicates in activated CD4 cells, which are typically destroyed in the process. However, some cells become infected when reverting to the resting state. When this occurs, HIV becomes integrated into long-lived-memory CD4 cells, a situation known as postintegration latency. These events begin early in infection, creating over time a reservoir of latently infected cells. These cells are sheltered from the immune system; because they are transcriptionally inactive, they are not eradicated by current ARTs.

The molecular mechanisms involved in the establishment of latency have not been fully elucidated. Although it is generally believed that the virus exists in a transcriptionally silent state, recent work indicates that although the “latent” genome is transcriptionally active, the viral transcripts are retained in the nucleus.82 Certain conditions within resting T cells inhibit HIV gene expression—for example, some of the host transcription factors (NF-κB and nuclear factor of activated T cells) necessary for gene expression are absent. Recent evidence also indicates that exposure of quiescent cells to certain cytokines can induce those cells to move along the cell cycle to the G1 phase, thus removing barriers to reverse transcription. Such cells are therefore susceptible to HIV infection but do not undergo full activation and cell cycling. Infection of quiescent cells may thus establish a repository of infected cells, maintaining a reservoir of HIV that exists for many years.83,84 Infected individuals harbor approximately one latently infected cell per million resting CD4 cells. Although the size of the infected cell pool is relatively small, it has the capacity, upon activation, to become transcriptionally active and to release virions into the lymphocyte circulation. The frequency of these cells tends to remain stable for years and is minimally affected by ART.85,86

Monocytes and tissue macrophages are also considered to be important cellular components of viral persistence and latency.87,88 The general consensus is that macrophages within the central nervous system serve as a reservoir of HIV infection. It is unclear, however, whether the reservoir comprises long-lived HIV-infected microglial cells or whether the reservoir is continually replenished by infected monocytes migrating from the periphery. Other potential reservoirs of infection include sites within the genital tract89,90 and possibly the kidney.91

Research has shown that neither the prolonged use of ART nor strategies to activate expression of virus from these reservoirs (by activating T cells through the T-cell receptor or with IL-2) have been successful in eradicating virus from the reservoirs, though the amount of virus may decrease slightly.92-94 An added concern is that mathematical modeling and limited experimental evidence suggest that pharmacologically induced high-level T-cell stimulation not only is unlikely to eliminate the T-cell reservoir but could potentially result in T-cell depletion as well.95
**CORRELATES OF DISEASE PROGRESSION**

The majority of HIV-infected individuals remain asymptomatic and maintain good viral control for a number of years before CD4 cell loss allows viral escape and opportunistic disease. This situation occurs in 85% of individuals; without ART, a period of 7 to 10 years passes before full-blown AIDS occurs. A smaller percentage of individuals (5%–10%)—a group known as “rapid progressors”—display poor viral control, rapid loss of CD4 cells, and rapid disease progression. At the other end of the disease spectrum is a group that displays a slow progression to disease. This latter group, comprising 5%–10% of infected individuals, is referred to as “long-term nonprogressors” (LTNPs) or “elite controllers.”

**FACTORS INFLUENCING THE IMMUNE RESPONSE**

The immunological events that take place at various stages of HIV disease were discussed in the preceding sections. The following section covers factors that influence the immune response at the various stages of disease.

**Host Genetic Factors**

Differences in host genetic composition may also affect the immune response and, consequently, the rates of disease progression. Polymorphisms in the chemokine co-receptors necessary for viral entry have been associated with differing rates of disease progression. These polymorphisms are seen in people who are heterozygous for the delta-32 base pair deletion in the CCR5 open reading frame. These individuals are characterized by decreased expression of cell surface CCR5, lower viral load, and slower disease progression. Viral peptides are presented to the immune system for recognition in association with HLA alleles, and certain HLA alleles may vary in their efficiency of antigen presentation. It has also been shown that even a single substitution in an HLA molecule can determine peptide binding and presentation. Certain HLA class-1 alleles have been associated with a greater risk of disease progression, such that patients with a greater heterozygosity in HLA class-1 alleles have demonstrated better outcomes. In essence, this would imply that patients with a broader immune response enjoy a better prognosis. Certain HLA backgrounds have been associated with protection against HIV infection; these backgrounds have been described in seronegative partners of HIV-infected individuals and in certain groups of sex workers who have been resistant to infection (see later in this chapter). For instance, a study of seronegative sex workers in South Africa found a clustering of HLA-A24 that was not found in HIV-infected women, suggesting that this allele may confer protection. Certain HLA molecules (e.g., HLA-B27 and HLA-B14) are associated with an immunodominant state, which results in a slower progression to AIDS. In these cases, the slow disease progression results from the HLA recognition of immunodominant epitopes, leading to a restriction in the viral diversity within the viral quasi species and thus in greater immune control. This, in turn, leads to a lower viral set point. In contrast, HLA-A29 and HLA-B22 are significantly associated with rapid progression to AIDS, possibly a result of limited antigen presentation. A persuasive example of the influence of the HLA system on the immune control of HIV infection is seen among LTNPs, or elite controllers, among whom there is a significant association with HLA-B*57.

**Immune Activation**

As stated earlier, immune activation plays a key role in the pathogenesis of HIV infection, as seen in resource-limited settings, in particular in sub-Saharan Africa. Activation of the immune system is a necessary component of the body’s response
to invading organisms. However, if the immune activation is excessive or prolonged, a number of negative consequences may occur. This excessive immune activation occurs in HIV infection because of the ongoing mutation and evolution of the virus within the quasi species. The negative effects of excessive immune activation include upregulation of HIV replication, driven by proinflammatory cytokines and leading to CD4 cell loss; integration of unintegrated viral RNA; apoptosis of uninfected cells; and polyclonal stimulation of B cells, with production of high levels of immunoglobulins.103,104

The immune activation noted in HIV-infected individuals is probably multifactorial in nature. The first factor is the direct effect of HIV on T cells. The interaction between gp120 and the CD4 or CCR5 molecule can induce intracellular signaling.105 The second factor inducing systemic immune activation is the host immune response to HIV. This activation is likely to be initiated at the innate immune system level, involving plasmacytoid dendritic cells through TLR stimulation, resulting in adaptive HIV-specific humoral and cellular responses.106 A further mechanism of immune activation relates to the translocation of intestinal microbial products from the intestinal lumen to the systemic circulation, where they can cause immune activation by binding to TLRs.4,107 Other pathogens, including opportunistic pathogens, play an additive role in promoting immune activation.108 It has also been shown that helminth infections, which cause immune activation, may result in enhanced disease progression.109 Another potential factor is the non-antigen-specific bystander activation of T and B lymphocytes caused by increased stimulation of proinflammatory cytokines. This activation results in these cells becoming prone to activation-induced cell death.110,111

At the molecular level, there is an increase in the number of CD8 cells bearing activation markers such as CD38 and HLA-DR. High expression of these activation markers is seen at the time of seroconversion. High levels of CD8/CD38 expression has been noted in the presence of high viral loads and serve as an independent prognostic marker.112-114 A further measure of the state of immune activation is reflected in the levels of inflammatory cytokines in HIV-infected subjects. Plasma levels of TNF-α, IL-1, and IL-6 are often elevated in later stages of HIV infection, and both TNF-α and IL-6 levels are directly correlated with plasma HIV RNA levels.115 With the administration of ART, measures of immune activation decrease, further supporting the hypothesis that the activation is related to viral replication.

States of immune activation are more commonly encountered in African populations than among populations in developed countries.116 This is due to the high levels of immune system activation seen in settings where there is a high burden of endemic infectious diseases, such as tuberculosis, respiratory infections, schistosomiasis, and various sexually transmitted infections (STIs).117 In the case of STIs, activated lymphocytes are found both systemically and at the site of infection and are associated with genital ulceration, which facilitates the acquisition and dissemination of HIV infection. Helminthiasis has also been associated with significant immune activation in African subjects.

With the introduction of ART, a significant and rapid decrease in activation markers occurs. A drop in the viral load is associated with a decrease in CD38/HLA-DR+, CD38/CD45RO+, and HLA-DR+CD45RO+. In this instance, the RO surface marker refers to the marker that identifies memory cells, and the CD45+ marker is found on all leucocytes.

**Viral Subtype**

The proinflammatory cytokines have been shown to upregulate HIV replication due to the binding of nuclear factor kappa B (NF-κB) to a consensus sequence in the core enhancer region of HIV’s long
terminal repeat (LTR). Studies have shown that the NF-κB enhancer configuration and copy number differ among subtypes. In subtypes B and E, one or two NF-κB consensus sequences are present in the viral LTR’s core enhancer region. In subtype C, however, three or more NF-κB consensus sequences have been reported. Thus, in subtype C, the potential exists for greater cytokine-driven viral replication. The resultant higher viral loads could, in turn, result in greater disease progression.

During primary HIV infection, a massive depletion of CD4 memory cells occurs in the GALT. In simian HIV (SHIV)-infected macaque monkeys, the viral RNA of the SHIV chimera bearing the subtype-C promoter predominated in feces and serum during primary infection. The subtype-B promoter, however, was found predominantly in peripheral blood mononuclear cells. Viral RNA in the feces reflects viral production in GALT. The action of cytokines, such as IL-2 and IL-15, in the intestinal environment can upregulate HIV replication by interaction of these cytokines with the NF-κB binding sites. This interaction may translate into differences in disease progression due to higher viral loads. It has been noted that there is a slower disease progression in subtype-A infections, with significant differences observed in viral load at peak viremia during acute primary infection, and at the viral set point.

**Malnutrition**

Malnutrition, an endemic problem in resource-limited settings, is an important underlying cause of childhood deaths, as well as an aggravating factor in a number of infectious diseases among adults. Malnutrition alters all defense mechanisms, including anatomical barriers, cell-mediated responses, phagocytic and microbicidal functions, and humoral functions (both antibody and complement). A reduction in the opsonic capacity of serum, diminished avidity of antibodies, inhibition of neutrophil and macrophage migration, and reduced intracellular killing capacity of phagocytic cells have also been recorded in individuals suffering from malnutrition. Secretory immunoglobulin A (sIgA) levels in these individuals are also decreased, which can lead to increased bacterial colonization of the respiratory epithelium.

The cellular immune defects observed in malnourished children include involution of the thymus gland, with a decrease in thymus-derived lymphocytes, leading to an impairment of T-dependent antibody responses and an imbalance of the Th1/Th2 axis. HIV infection, in turn, also causes several metabolic disturbances, including changes in whole-body protein turnover, increased urinary nitrogen loss, and skeletal muscle breakdown, which further compromise the nutritional deficit.

A feature of HIV infection is a depletion of micronutrient status. These micronutrients include selenium, zinc, magnesium, vitamin E, cyanocobalamin, vitamin C, folic acid, and niacin. All of these factors play a key role in various immune processes, as well as in the functional and structural integrity of epithelial tissues. They are also involved in DNA synthesis, hemopoiesis, and decreasing oxidative stress in tissues.

**Age at the Time of HIV Infection**

Data from a number of cohort studies indicate that the risk of disease progression and mortality can be correlated with age, after adjusting for CD4 counts and plasma HIV RNA levels.

**Interaction between HIV and Malaria**

The interaction between HIV and malaria has important public-health implications in resource-limited settings, particularly in sub-Saharan Africa, where there is a high prevalence of both infections. HIV infection impairs the cell-mediated immunity that is crucial for antimalarial responses. In areas of stable malaria transmission, such as Uganda,
malaria infection rates and frequency of clinical illness appear to be increased in HIV-infected adults, particularly those with low CD4 counts. For instance, a study in urban Malawi found an increasing incidence of clinical malaria with significant parasitemia when CD4 counts decreased, suggesting an inverse relationship between parasite density and CD4 count. Studies suggest that HIV-associated immunosuppression interferes with parasite control and a loss of specific protection against malaria-driven disease.

In regions of unstable malaria transmission, HIV-infected adults are at an increased risk of complicated and severe malaria and death. This is significant because more than half of the global burden of malaria is in hypendemic and mesoenemic regions. For instance, studies in South Africa have reported a doubling of the risk of complicated malaria and a fivefold increased risk of death in HIV-infected adults. An additional factor is the prolonged clearance times for parasitemia following malaria treatment in HIV-infected adults. A study in Malawi, examining the effect of malaria on HIV disease, demonstrated up to a 10-fold increase in HIV viral load among patients with malaria. This effect was correlated with the level of parasitemia and clinical severity of disease. Such increases in viral load will lead to CD4 cell loss, which is likely to influence the progression of HIV disease.

LESSONS LEARNED FROM SPECIAL GROUPS

Highly Exposed, Persistently Seronegative Individuals

In most settings, highly exposed, persistently seronegative (HEPS) individuals have been identified who, despite repeated exposures to HIV, have remained seronegative. The immune response among HEPS may provide important clues regarding the dominant correlates of immunity that could potentially assist vaccine development. The mechanisms of protection among HEPS remain unclear, and there may be more than one possible pathway. For instance, in some individuals, there is evidence that an abortive infection has occurred, while in others, there may be a true resistance to infection.

Low levels of CD8 cells reactive to HIV peptides have been found in groups of high-risk seronegative individuals. A study from Gambia among a group of sex workers reported that detectable CTL responses were seen in three of six HEPS individuals, suggesting that infection had occurred but had been cleared. Another study in Nairobi demonstrated the presence of mucosal anti-HIV CTLs in individuals who remained seronegative, despite repeated high-risk exposures. Humoral responses have also demonstrated immunological memory to HIV. Specifically, mucosal immunoglobulin A (IgA), capable of cross-clade HIV binding and neutralization, has been found in genital secretions of some high-risk uninfected individuals. It has also been postulated that some exposed seronegative individuals may actually harbor low levels of virus or that repeated exposures continually boost these immunological responses, hence promoting ongoing protection. The latter hypothesis may be supported by findings from a group of sex workers who ceased commercial sex work for a period of time and then became infected once they recommenced their high-risk exposures.

Earlier experiments provide compelling evidence that CTLs from HEPS individuals provide protection. In a series of experiments, CTLs that were transferred to severe combined immunodeficiency (SCID) / beige mice provided protection to subsequent HIV challenge. Yet not all HEPS individuals display these CTL responses, suggesting that protective factors are also at work.

Genetic influences also play a protective role, such that individuals who are heterozygous for
the deletion of the CCR5 gene are relatively resistant to infection. Just as certain HLA backgrounds have been associated with HEPS sex workers, they may also play a role in protection. For instance, an increased frequency of HLA-B18 and HLA-A11 have been found in sex workers in Thailand. Increased frequency of HLA-B18 has also been found in the Nairobi, Kenya, HEPS cohort. In KwaZulu-Natal, South Africa, a higher frequency of HLA-A68 was noted in uninfected or HEPS individuals.\textsuperscript{135}

**Long-Term Nonprogressors**

LTNP, or elite controllers, make up approximately 5%–10% of HIV-infected individuals.\textsuperscript{20(pp301-330),143} This group also provides important insights into the correlates of immune control of HIV and can thus inform HIV vaccine design. The LTNP, as a group, are fairly heterogeneous, with the following common characteristics:

- Have had HIV infection for 10 years or longer
- Are asymptomatic
- Are not on ART
- Have normal or stable CD4 counts
- Have strong cellular immune responses
- Have good neutralizing antibody responses
- May have genetic profiles associated with delayed progression

**ADDITIONAL CONSIDERATIONS**

**Superinfection**

For a long time, it was assumed that individuals infected with one strain of HIV would be resistant to infection from another strain. Yet the ever-increasing number of circulating recombinant forms (CRFs) provide ample proof that “superinfections” are not a rare curiosity, but rather a more frequent phenomenon than was previously realized. These superinfections hold important implications for the clinical management of disease, as well as for vaccine design.

**Monitoring of Immune Status**

The hallmark of HIV disease is the destruction of CD4 lymphocytes. Thus, the most commonly used test for measuring individual immune status is the CD4 count, which clinicians use to define the stage of HIV infection; to determine when to initiate chemoprophylaxis against opportunistic infections (e.g., *Pneumocystis jiroveci* pneumonia) and to commence ART; and to monitor response to treatment. The AIDS diagnosis is made in individuals with a CD4 count of 200 cells/mm\(^3\) or less or a CD4 percentage of less than 14%. There is considerable variation among patients in the loss of CD4 cells, with an accelerated loss seen in patients with higher viral loads or in patients with coexisting morbidities (e.g., tuberculosis). CD4 percentages are less variable than are CD4 counts and are important to take into account when assessing immune function, particularly when comparing results performed on different platforms or by different laboratories.

The gold standard for measuring CD4 cells is flow cytometry, a technique that is often beyond the reach of facilities in resource-limited settings because of its high cost and the need for trained laboratory personnel. Simpler, lower-cost strategies for CD4 testing in resource-limited settings are currently being developed. Total lymphocyte count (TLC) has been used, with limited success, as a surrogate for CD4 counts. However, the reference ranges used for CD4 and CD8 counts are currently being developed. Total lymphocyte count (TLC) has been used, with limited success, as a surrogate for CD4 counts. However, the reference ranges used for CD4 and CD8 counts are often based on analysis of samples from healthy individuals in developed countries, and there is a paucity of reports containing reference ranges from African countries, where it is thought these parameters may differ.\textsuperscript{144} This theory is supported by a study in Abidjan, Côte D’Ivoire, in which the absolute CD4 counts of HIV-infected individuals were found to be higher than in HIV-infected patients in France.\textsuperscript{144} Similar discrepancies have been noted in other African populations when compared with their counterparts in Europe or North America.\textsuperscript{145}
A number of factors influence CD4 counts, including age, sex, diurnal variations, exercise, and certain drugs. In pediatric populations, CD4 percentages are used for clinical management decisions due to the wide variation in absolute CD4 counts in this age group. In summary, it is important to establish local CD4 and CD8 reference ranges based on local or regional data, rather than simply using the potentially inappropriate ranges provided by test kit manufacturers.

**Immune Reconstitution Following Commencement of Antiretroviral Therapy**

When viral suppression is achieved after the initiation of ART, reconstitution of the immune function is possible. This reconstitution may manifest as the disappearance of opportunistic infections and the restoration of delayed-type hypersensitivity (DTH) to recall antigens. The capacity for more optimal immune restoration relies on antiretrovirals (ARVs) being initiated before the immune system has sustained advanced viral damage. Sustained viral suppression is associated with a decrease in activation markers (i.e., CD38 and HLA-DR+ cells) and a progressive increase in CD4 cells. There is a biphasic increase in CD4 cells, with the initial increase being related to a release of memory cells from lymphoid tissues bearing the CD4/CD45RO+ marker. This is followed by a slow and steady increase in naïve CD4 cells that display CD4/CD45RA+ markers.

Current guidelines for developing countries suggest that initiation of ART should take place when an individual has a CD4 count below 200 cells/mm$^3$ and/or an AIDS-defining condition. However, an ever-increasing body of evidence suggests that in these settings, earlier initiation of treatment will lead to more comprehensive restoration of immune function. For instance, a recent study showed that patients commencing ART at baseline CD4 counts higher than 350 cells/mm$^3$ regained nearly normal CD4 counts after six years of therapy.147,148

**Immune Reconstitution Inflammatory Syndrome**

The suppression of HIV replication following ART allows for recovery of the immune system and restoration of pathogen-specific immune responses. In some cases, this is accompanied by immunopathological reactions and clinical deterioration.149,150 This condition is termed immune restoration disease, or immune reconstitution inflammatory syndrome (IRIS), and has been reported in relation to a number of pathogens and autoimmune phenomena. In states of severe immunodeficiency, pathogens are not eradicated from tissues; instead, they remain latent or dormant and do not elicit an inflammatory response. Restoration of pathogen-specific immunity causes either local or generalized inflammatory changes. IRIS has been reported with mycobacterial infections, cryptococcal disease, hepatitis B and C, cytomegalovirus infections, varicella zoster, herpes simplex, and pneumocystis infections.

Tuberculosis (TB) is the most common opportunistic infection of HIV-infected individuals in sub-Saharan Africa. There are two distinct forms of IRIS associated with TB.150,151 Paradoxical IRIS occurs in individuals who have had a diagnosis confirmed and who are receiving (or have completed) anti-TB treatment. In this form, shortly after commencing ART, there is a paradoxical worsening or recurrence of TB symptoms, signs, or radiological features. The other form of IRIS, called “unmasking IRIS,” occurs when an unrecognized TB infection is revealed after the patient is initiated on ART. In this instance, TB is occult and unrecognized because of profound immunodeficiency. Once ART is commenced, the immune restoration leads to the unmasking of TB.
AIDS Vaccine Development

In this third decade of the AIDS pandemic, the goal of developing an effective preventive vaccine remains elusive. Traditional viral vaccines allow the respective virus to enter the body of vaccines, and then the vaccine-generated immune processes deal with the invading organism. In HIV infection, however, the integration of HIV into the genome of the target cells within the mucosa or adjacent lymphoid tissues allows a very limited window of opportunity for vaccine-induced immune responses to be protective.

Efforts to develop a vaccine initially focused on the HIV viral envelope, which is the target of neutralizing antibodies in HIV-infected people. It was hoped that neutralizing antibodies would be generated that could bind to the envelope, neutralize the virus, and clear the infection before it became established. Yet when these vaccines were tested, they failed to protect healthy subjects from HIV infection. One reason for this was that the gp120 protein undergoes significant conformational change on interacting with the CD4 receptor, thus exposing hypervariable regions. In this scenario, it is easy for escape mutants to be generated, resulting in a loss of protection.

With new insights into the pathogenesis of HIV, attention was drawn to the effect of cellular mechanisms that control viral replication. Although there is a considerable body of evidence regarding the role of CD8 CTLs in controlling viremia, there has been no observed effect on the latently infected CD4 reservoir, which escapes immune surveillance.

If the goal of a preventive vaccine remains elusive, then the question of whether partial protection offered by a vaccine could potentially alter the course of HIV disease must be answered. A lower viral set point is known to confer a survival advantage. In addition, it is possible that pre-existing immune responses may provide protection from the devastating GALT CD4 cell loss that occurs during acute primary infection. In addition to the benefit to the individual, there may also be a public-health benefit from a partially protective vaccine. For instance, the HIV epidemic is driven by transmission of virus by individuals who are in the early phases of disease progression, a period associated with high viral loads. If a vaccine were successful in reducing the viral loads of HIV-infected individuals during the early acute phase of infection, this might, in turn, confer some protection to the general population.

A number of vaccine trials are currently underway that use priming immunization with a vector approach to stimulate cellular immunity, followed by booster immunizations to promote antibody production. However, a recent setback occurred when the HIV Vaccine Trials Network studies HVTN 502 and 503 (Phambili study, South Africa), based on the Merck candidate vaccine MRKAd5 HIV-1 gag/pol/nef construct, had to be prematurely discontinued. The vector used was an attenuated adenovirus, which is normally responsible for the common cold. The randomized, double-blind, placebo-controlled Phase IIb study was halted prematurely because the Data Safety and Monitoring Board, upon reviewing the preliminary data, found that the HIV infection rates were similar in both the test and the placebo groups. The viral load estimations in both groups were also found to be similar.153

Immunology of HIV-1 and the Host Response in Children

Sibyl Geelen\textsuperscript{a,b} and Debbie van Baarle\textsuperscript{c}

\textsuperscript{a}Department of Pediatric Immunology and Infectious Diseases, University Medical Center Utrecht, the Netherlands
\textsuperscript{b}Center for Poverty-Related Communicable Diseases, PharmAccess Foundation, the Netherlands
\textsuperscript{c}Department of Immunology, University Medical Center Utrecht, the Netherlands

The majority of children living with HIV-1 (hereafter abbreviated as HIV) acquired the infection perinatally via mother-to-child transmission. Because the host in this scenario has an immature and developing immune system,\textsuperscript{1} the virological and immunological characteristics of HIV infection in infants and young children differ significantly from those in older children and adults. Persistence of HIV viremia occurs at high levels during the first years of life and, in many infants and children, rapidly causes a profound failure of the young child’s immune system.

Before the introduction of combination anti-retroviral therapy (ART), roughly 20% of HIV-positive infants living in Europe suffered a serious CD4 T-cell loss and clinical deterioration within the first year of life, resulting in severe HIV-related manifestations; nearly 30% of infected children died before the age of five years.\textsuperscript{2} A recent analysis of the clinical course in more than 3,000 untreated HIV-positive infants from different countries in sub-Saharan Africa showed an even worse prognosis, with a mortality rate greater than 50% by two years of age. Infants with early perinatal infection acquired before the age of four weeks appeared to have a particularly great increase in mortality risk.\textsuperscript{3} This finding was confirmed by other researchers, who reported that 85% of intrauterine- and intrapartum-infected infants showed a rapid decline in CD4 T cells and met the criteria for initiating ART within six months after birth.\textsuperscript{4} In contrast, some perinatally HIV-positive children live for more than 10 years without serious clinical manifestations. The mechanisms behind these differential disease patterns have not yet been elucidated, but both virological and immunological characteristics appear to be relevant.\textsuperscript{5,6}

This chapter provides an overview of the current knowledge on the constitution of the immune system and host responses toward HIV and common microorganisms in HIV-positive children before and after starting ART.

CD4 and CD8 T cells in healthy infants and children

Physiologically, newborns have much higher absolute numbers and percentages of CD4 T lymphocytes than do older children and adults. A gradual decrease in CD4 T cells is observed during the first six years of life.\textsuperscript{7} Infants up to three months of age have a median CD4 T-cell percentage of 52%, and this decreases to a median of 37% by age 6 to 12
It has been demonstrated that absolute CD4 T-cell numbers vary more with age than do CD4 percentages. CD8 T lymphocytes also change markedly during the first years of life. An increase from a median of 16% at age three to six months to a median of 26% at age 12 to 18 years has been reported.7,8

During infancy, fresh naive T cells are continuously released from the thymus, and since children constantly encounter new antigens in their first years of life, the compartment of previously activated CD4 and CD8 T cells and memory T cells increases progressively.7 T-cell receptor excision circles (TRECs) can provide insight into the replicative history of T cells. TRECs are stable circular DNA fragments that are formed as by-products during T-cell receptor gene rearrangements in the thymus. They are not replicated upon further division of cells but pass to one of the two daughter cells. Thus, the TREC content of T lymphocytes has been used as a marker of T-cell proliferation.9 Several studies have found that the TREC content per lymphocyte decreases with age.10,11

Various reports indicate that race-related differences and environmental factors may influence the levels of these immunologic parameters. Total lymphocyte numbers and CD4 and CD8 subset values were generally found to be lower in healthy black children than in healthy white children.12-15 And in comparison with black children living in Europe, black children living in Uganda had lower CD4 T-cell values, whereas no significant differences were found between their CD8 T-cell and total lymphocyte values.4 Lower CD4 T-cell counts and especially lower naive CD4 T-cell counts also have been reported in healthy Ethiopians.16,17 However, in a group of Ethiopian infants and children it was documented that these differences were not yet present at birth, but rather developed over time. A recent study sheds light on this remarkable finding. It was demonstrated that the numbers of CD4 and CD8 T cells at birth in Ethiopian neonates were similar to those in Dutch neonates. Moreover, no differences at birth were found for the TREC content of lymphocytes, or the number of naive T cells. However, significant differences developed between Ethiopian and Dutch children already at a young age and persisted into adulthood. These age-dependent differences were associated with a higher baseline level of activated T cells in the Ethiopian individuals. It was hypothesized that the higher level of immune activation was caused by a higher antigenic exposure (e.g., to parasites) occurring in Ethiopians shortly after birth and well into adulthood.18

The mounting evidence that CD4 T-cell values differ between populations living in different environments complicates the use of this marker as the main immunologic parameter for starting and monitoring HIV treatment, emphasizing the need for population-specific baseline values for this and other childhood parameters.

**Immune System During HIV Infection in Infants and Children**

The hallmark of HIV infection, in both adults and children, is depletion of CD4 T cells. The progressive loss of CD4 T cells, key coordinators of the immune function, undermines both the humoral and cellular arms of immunity. As in adults, various patterns of CD4 T-cell loss and clinical disease progression have been observed among children. It has been postulated that CD4 depletion in the periphery is caused by persistent immune activation during the HIV infection, which results in continuous proliferation of T cells, thereby exhausting the naive T-cell pool. It is well known that CD4 depletion occurs more rapidly in infants and children than in adults. This finding is remarkable in light of an active thymus present in infants and young children that can produce naive T cells and may therefore be expected to be well equipped.
to compensate for the loss in naive T cells at the periphery. However, studies on the dynamics of naive and memory T cells in healthy and HIV-positive children demonstrated that healthy children had an age-related increase in the total body numbers of naive and memory T cells, whereas absolute numbers of TREC’s remained stable.\textsuperscript{19} The proportion of dividing naive T cells was high, especially in younger children, which indicated that the expansion was the result of proliferation, in addition to antigen-mediated naive T-cell activation leading to the formation of memory T cells.

On the basis of these results, it was concluded that the expansion of the naive T-cell pool after birth was more dependent on T-cell proliferation than was previously recognized.\textsuperscript{19} In untreated children infected with HIV, total body numbers of T cells and TREC’s were significantly reduced compared to the levels in healthy children. In contrast, T-cell division levels of both naive and memory T cells were much higher than those in healthy children. This indicated that, similar to HIV infection in adults, continuous activation of naive T cells significantly contributes to the erosion and exhaustion of the naive T-cell pool and progressive loss of CD4 T cells during HIV infection in children.\textsuperscript{19}

These events take place during the growth of the infant body, which, under normal conditions, is already in need of both a continuous supply of new T cells from the thymus and an active proliferating peripheral T-cell pool to meet the requirements for control and defeat of commonly encountered microbes and other antigens. Moreover, as will be discussed, immune control by the effector cells of the immune system, which is important for limiting HIV replication, is not yet fully developed, and thus these cells are unable to limit the constant and vigorous activation of the CD4 T cells by HIV itself. Altogether, this may explain the more rapid loss of CD4 T cells in infants and young children.

**HOST IMMUNE RESPONSE TO HIV-1 AND OTHER PATHOGENS**

**Antibody Responses: HIV-Specific Antibodies**

Following acute infection, neutralizing antibodies against various HIV gene products are generated in older children and adults. These antibodies have been detected from day 28 on, but they are unable to control the HIV infection.\textsuperscript{20-21} In fact, a poor correlation between neutralizing antibody response and disease progression has been found.\textsuperscript{23,24} This may be explained by the continuous emergence of neutralizing escape mutants as a result of selective pressure by the potent neutralizing antibody response.\textsuperscript{21,22}

Moreover, neutralizing antibodies do not arise prior to the fall in plasma viral load as occurs in acute HIV infection. It was suggested that envelope-binding antibodies, generated before the appearance of neutralizing antibodies, may play a role in reducing the viral load by effector functions other than direct neutralization.\textsuperscript{25}

IgG antibodies actively pass through the placenta during pregnancy, and vertically infected infants have maternally derived, specific HIV antibodies. Active production of functional antibodies, however, starts only after one year of age.\textsuperscript{26}

A few studies in children have evaluated the association between the presence of neutralizing antibody levels and the clinical course. In some studies, a better clinical condition was found in the infants of mothers with higher levels of neutralizing antibodies.\textsuperscript{27,28} The same association was found for antibodies mediating cellular cytotoxicity.\textsuperscript{27}

**Antibodies to Other Microbes and Vaccination Antigens**

As in adults, HIV infection in children is characterized by high levels of immunoglobulins (hyper IgG, hypergammaglobulinemia). This phenomenon
probably results from a continuous antigen-driven stimulation of naive B cells, leading to a state of hyperactivation with the production of low-avidity antibodies (i.e., antibodies that interact only weakly with their antigen). In contrast, B-cell function becomes defective and the ability to produce specific antibodies is impaired.

The production of specific antibodies requires a smooth interaction between various components of the immune system: antigen-presenting cells, B lymphocytes, and T lymphocytes. Dendritic cells, as all antigen-presenting cells, initiate T- and B-cell activation by processing antigens and presenting them on their surface for recognition by specific CD4 T cells. The percentage of plasmacytoid dendritic cells was shown to be decreased in children infected with HIV, and the function of these cells, as measured by their ability to produce interferon alpha, was also profoundly impaired.

To be able to mount an adequate antibody response to the majority of antigens, B cells require the help of CD4 T cells. Cytokines produced by CD4 T cells stimulate the B cells to differentiate into immunoglobulin-producing B cells or memory B cells. Thus, CD4 T-cell depletion due to HIV infection results in insufficient B-cell activation and differentiation. This explains why pathogens against which antibodies play a crucial role in defense can potentially cause serious infections in HIV-positive children and adults.

It has also been demonstrated that the response of HIV-positive children against various vaccination antigens is decreased as compared to healthy children. Moreover, during the course of the HIV infection, the responsiveness toward various vaccination antigens wanes with time. This phenomenon has been demonstrated for diphtheria, tetanus, measles, mumps, rubella, pneumococci, and Hemophilus influenzae type B. In addition, antibodies to naturally occurring pathogens, such as varicella zoster virus (VZV) and cytomegalovirus (CMV), also decrease. Loss of CD4 T helper cell function, as well as loss of memory B cells by apoptosis, appears to be responsible for this phenomenon.

CURRENT IMMUNIZATION PRACTICES IN HIV-POSITIVE CHILDREN

Although the ability to mount antigen-specific immune responses to vaccination antigens may be suboptimal in HIV-positive children, and especially in those with a more advanced stage of immunodeficiency, these children may still benefit from routine vaccinations. The World Health Organization (WHO) advises routine vaccinations for HIV-positive children, with modifications for those with symptomatic HIV infection. Asymptomatic children can be safely immunized with diphtheria, tetanus, poliomyelitis, and hepatitis B vaccine, consisting of inactivated components, and also with measles, oral poliomyelitis, and yellow fever vaccine, consisting of live attenuated viruses. For measles, the first vaccination is usually administered at the age of 9–12 months, but for HIV-positive children, an extra dose at the age of 6 months is advised to provide protection at a younger age.

WHO advises the administration of BCG (bacille Calmette-Guérin) vaccine at birth to all infants in countries with high TB exposure rates, but cautions that this vaccination should be withheld for infants suspected to be HIV-positive in countries where there is a low risk of acquiring TB. Symptomatic children should not receive yellow fever vaccine.

The U.S. Advisory Committee on Immunization Practices (ACIP) recommends against the use of BCG and yellow fever vaccine in all HIV-positive children, whether asymptomatic or not, and also recommends against administering the measles
vaccine to children with CD4 T-cell levels less than 15%. Moreover, ACIP recommends the use of inactivated poliomyelitis vaccine rather than the oral vaccine containing live virus.44

**ROLE OF THE INNATE IMMUNE SYSTEM**

Insight into the contribution of the innate immune system in controlling HIV infection is only beginning to emerge. This part of the immune system is the first to come into action after HIV transmission, and observations in adults indicate that the innate immune system combats HIV at different levels during the disease.45,46 In healthy newborns, the innate immune mechanisms have been found to be impaired. For example, the production of pro inflammatory cytokines and the response of macrophages to interferon gamma (IFN-γ) were found to be deficient.47

Studies evaluating the different components of the innate immune system in HIV-positive children have been sparse. Conflicting data have been reported on the association between mannose binding lectin (MBL), a circulating pattern-recognition molecule, and disease progression. One study found no relation between low MBL levels and disease stage, while another reported MBL deficiency to be more frequent in a group of children with an advanced stage of HIV disease.48,49

A study on natural killer (NK) cells observed that the cytolytic function of neonatal NK cells may depend on the characteristics of the target cells. For example, decreased cytolytic NK cell activity was found for target cells infected with herpes simplex virus (HSV) or CMV, whereas the direct killing capacity of neonatal NK cells for HIV-infected cells was similar to that of adult NK cells.50-52 However, antibody-dependent NK-cell-mediated cytotoxicity of HIV-infected cells was inferior.52 During HIV infection, decreased levels of NK cells, in particular the subset of mature NK cells, were measured in HIV-positive adults as well as children.31,53

Plasmacytoid dendritic cells are also part of the innate immune system. These cells belong to the primary line of defense and are extremely important in initiating an immune response. As stated previously, both the percentage and function of these dendritic cells were decreased in children infected with HIV.31 It is therefore likely that the lack of proper innate immune mechanisms contributes to the inability to control HIV infection after vertical transmission.

**ADAPTIVE CELLULAR IMMUNE RESPONSE: CYTOTOXIC T CELLS**

Antigen-specific cytotoxic T lymphocytes (CTLs) play an important role in clearing acute viral infections and containing chronic viral replication in humans. In healthy infants, the function of these effector cells of the immune system may be deficient or deviant, which explains why some acute viral infections run a severe clinical course while other viral infections (such as hepatitis B and HIV) tend to establish an ongoing chronic disease in infants after perinatal transmission.54

In adults, HIV-specific CTLs usually emerge during the first weeks of HIV infection and appear to play a crucial role in limiting infection and disease progression by partial immune control.55 The level of CD8 T-cell activation in early infection is an independent predictor of the rate of CD4 T-cell decline in adults.56 Several earlier studies have reported on the function of cytotoxic CD8 T-cell responses in children. Cytotoxic T-cell responses were weaker or absent in almost all infants younger than six months of age, whereas CTL responses in older children were comparable to those in adults.57-59 Evaluation of specific cytotoxic responses against HIV proteins in a group of vertically infected children demonstrated that the majority of asymptomatic children had detectable cytotoxic
were less pronounced in HIV-positive adults and children.\textsuperscript{64,65}

The mechanisms behind these weaker and different cytotoxic T-cell responses against HIV in infants have not yet been elucidated, but could be due to partial HLA (human leukocyte antigen) compatibility between mother and child. HIV antigens are processed by infected cells, and fragments are presented on the surface of the cells by HLA class I molecules for recognition by CTLs. It has been shown that CTL escape can occur during HIV infection, leading to a decrease in CTL responses against the HIV mutant variant either because the HLA molecule cannot bind the antigen of the HIV variant anymore, and thus it cannot be presented, or because the HIV variant interferes with CTL recognition.

As children’s HLA is at least 50% identical to maternal HLA, and as the virus has been under maternal CTL immune pressure, transmission of an HIV CTL escape variant may hamper the development of proper immune responses. A study elegantly showing this was performed by Goulder et al in which mother-to-child transmission was studied in the setting of HLA-B27 expression.\textsuperscript{66} HLA-B27 expression is associated with prolonged immune containment of HIV infection in adults, whereas a mutation in a dominant and highly conserved B27-restricted epitope of HIV resulted in a loss of HLA presentation, in failure to present the epitope to CTL, and in disease progression. The researchers showed that in mothers expressing HLA-B27 who transmitted HIV to their infants, viruses encoding for CTL escape variants in this dominant HLA-B27-restricted epitope were specifically transmitted. Instead of being able to recognize the normally susceptible wild-type epitope, CTLs of these infants targeted an otherwise subdominant HLA-B27-restricted epitope but subsequently failed to contain HIV replication.\textsuperscript{66} This mechanism may explain why HIV causes the persistent
high levels of viremia and rapid disease progression seen in a significant proportion of infants. In addition to preferential transmission of already escaped viruses, it was shown that additional viral escape mutants may also arise within the infants early after perinatal infection for HLA alleles that are not present in the mother. Mutations of an HLA-B57-restricted epitope were shown to arise in HLA-B57-positive infants, born to HLA-B57-negative mothers, further contributing to lack of viral control.

**CLASSIFICATION OF IMMUNODEFICIENCY IN HIV-POSITIVE CHILDREN**

The failing immune system in HIV-positive children allows microorganisms to flourish and cause disease. This results in aggravation of the common diseases of childhood, such as respiratory tract infections, and in opportunistic infections.

To define the stage of HIV infection and the need for ART, an age-related classification staging system and age-related therapy guidelines have been developed by WHO and by the Centers for Disease Control and Prevention (CDC). Both guidelines use CD4 T-cell percentages as a marker for the severity of immunodeficiency. The WHO classification system is the most widely used system in resource-limited settings (Table 1). It is important to note that a child’s CD4 T-cell values may vary in association with intercurrent illnesses. Serial CD4 T-cell measurements provide a more realistic view of the child’s immune status, and CD4 T-cell values should be determined at least twice before a decision to initiate ART is taken.

Threshold CD4 T-cell values for severe immunodeficiency are based on longitudinal data of HIV-positive infants and children in resource-rich settings. For children older than one year of age, these values correspond to a 12-month mortality risk of 5% or less. Younger infants, and especially those under the age of six months, have an increased mortality risk, even with higher CD4 T-cell percentages.

As discussed before, baseline immunologic parameters differ between populations. Whether the chosen threshold values are also appropriate for HIV-positive children in resource-limited settings is not yet clear, and this needs to be evaluated.

The WHO immunologic classification system also provides age-related total lymphocyte

values, indicative for immunodeficiency (Table 2).68 Several studies have indicated that the total lymphocyte count is a powerful predictor of the risk of disease progression. As such, it is a valuable marker that may be used to determine eligibility for ART in resource-limited settings where CD4 determination is not yet available.71,72

RESPONSES OF THE IMMUNE SYSTEM IN CHILDREN LIVING WITH HIV AND ON ART

Recovery of CD4 T Cells
Most children respond well to ART, and even children with advanced immunodeficiency generally show a rapid recovery of CD4 T cells and an improvement in their clinical condition, growth, and development.73-77 However, a recent study from Zambia of nearly 5,000 HIV-positive children, of whom almost 60% received ART, also indicated that an earlier initiation of ART than currently is recommended by WHO may be needed (especially in infants younger than 18 months) to prevent mortality in the first three months after the initiation of ART.77

Studies have found that total CD4 T-cell numbers and naive CD4 T cells increase more, and take place more rapidly, in younger children than in older children and adults. This phenomenon is attributed to the fact that younger children still have a functional thymus, whereas thymic output decreases after early childhood.78-80 However, it has also been shown that the relative gain of naive and total T-cell numbers is independent of age when numbers are normalized for age-matched controls.79,81 It is important to note that even children who start ART with a low baseline CD4 T-cell count generally recover to levels similar to those of age-matched controls, and often do so within the first year of therapy.82

Whether full recovery of CD4 T-cell counts could be achieved in all age groups has been debated for a long time. Recent data demonstrated that recovery of the total number of CD4 T cells is indeed possible in HIV-positive children and adults on long-term ART with sustained viral suppression.82 However, a difference was seen between adults and children with regard to naive CD4 T cells. While all the children had normalized numbers of naive CD4 T cells, this was not the case for adults who had started ART with low baseline CD4 T-cell counts.82 This finding indicated that recovery of the T-cell compartment may nevertheless be expected in children who have a more advanced level of CD4 T-cell depletion. Although this could be used as an argument to postpone ART to prevent adverse events associated with long-term use of antiretrovirals, it is obvious that decreasing CD4 T-cell levels are associated with an increasing risk of (opportunistic) infections. Thus, in order to prevent serious morbidity and mortality, early diagnosis of HIV infection is important, and ART should be initiated before serious immunosuppression occurs.

Recovery of Functional Immunity

In contrast to the excellent recovery of T-cell numbers in children, several studies indicate that the reconstitution of functional immunity may still be impaired. While being treated with ART, HIV-positive children still showed an increased loss of protective antibodies against vaccination antigens and, to a lesser extent, of antibodies against natural antigens. In 40% of children, declining antibodies against measles, mumps, and rubella (MMR) antigens were observed, while 21% of children lost antibodies against VZV and 7% against CMV. This is in contrast to findings in longitudinal studies of vaccinated healthy children, in whom antibodies against MMR could be detected in 86%-100% of children after 9-15 years of follow-up.83,85

Moreover, after stimulating the immune system with booster vaccinations, an adequate immune response was observed in only a portion (60%-85%) of the HIV-positive children. This is in agreement with other studies, in which HIV-positive patients who received tetanus toxoid booster vaccinations showed a moderate antibody response and subsequent waning of antibody titers in the following years.86,87

Different response patterns have been observed in children on ART who were vaccinated with pneumococcal vaccines as well. The best responses were observed in children with a higher CD4 percentage and maximally suppressed HIV virus.88,89 A study on varicella vaccine in children on ART showed a response rate of around 60% after a two-dose regimen, which is significantly decreased as compared to healthy, HIV-negative children, who demonstrated up to 100% conversion rates after a single dose of the VZV vaccine.90,91 Whether the antibody levels will persist in these children remains to be seen. Moreover, antibodies did not rise significantly in VZV-positive HIV-positive children on ART who experienced a wild-type VZV reinfection.90

Recovery of Specific Cellular Immunity

HIV-Specific Cellular Immunity

Several studies have evaluated specific CD4 and CD8 cellular immunity against HIV in children on ART. It was observed that cytokine-secreting patterns of HIV-specific CD4 T cells of chronically infected children with a continued and maximal suppressed viral load differed from those of children who experienced viral blips or had viremia despite ART.91 CD4 HIV-specific T cells of children with optimal suppression secreting mainly interleukine-2 (IL-2) in response to stimulation with the HIV gag protein, whereas HIV-specific CD4 T cells of the other children secreted predominantly IFN-γ or a mixture of IL-2 plus IFN-γ. Overall, the frequency of HIV-specific CD4 T cells in children was significantly higher compared with that of chronically infected adults. This observation, in addition to the high proportion of IL-2-secreting HIV-specific CD4 T cells in successfully treated children, indicated a greater capacity of children to restore functionally active CD4 helper T cells than adults.93

When HIV-positive children were vaccinated with hepatitis A vaccine, around half the children had low antibody levels after the regular two-dose vaccination regimen. The best responses were observed in the group of children with CD4 T cells greater than 20%. Improved antibody levels could be generated with a third vaccination.92 Altogether, these studies show that even after CD4 recovery on ART, the quality of the immune response may still be compromised. The immune system may therefore need a more powerful boost to mount an adequate response to antigens and, in the case of vaccine-preventable diseases, follow-up may be indicated to monitor whether antibody levels remain adequate.
the age of one year as compared to children who had started after two years. However, total CD8 T-cell responses in the younger age group were comparable to those of age-matched controls that were not treated with ART. This indicated that the lower responses were due to younger age. A broad diversity of CD8 T-cell responses targeted at various HIV antigens was observed in a group of children between 6 and 17 years of age on ART. The magnitude and breadth of these responses were comparable to those found in adults.

Specific Cellular Response to Other Antigens
Specific cell-mediated immunity to pathogens other than HIV may not recover completely after the initiation of ART, or only after reexposure to the antigen. For example, the cellular immune responses to VZV did not improve during the course of more than three years of monitoring in children on ART, despite effectively reduced viral load and restoration of CD4 T cells. Among the children who had responded well to ART, adequate in vitro cellular responses against VZV were documented only after they had developed herpes zoster. In contrast, the children who had not responded well to ART did not show a good immune response, even after developing herpes zoster. From these findings it was concluded that reconstitution of cellular immunity to VZV requires not only adequate control of HIV replication, but also antigenic reexposure. A recent vaccination study showed that the serological response after VZV vaccination was significantly less in clinically stable HIV-positive children on ART as compared to their HIV-negative siblings. Moreover, a relatively high number of VZV reinfecions occurred in these children and VZV antibody titers did not rise significantly after the natural infection.

When evaluating the cellular immune responses to CMV it was expected that endogenous boosting by frequent CMV reactivation would promote the recovery of CMV-specific cellular responses. However, this was not observed in the study group of 35 CMV seropositive HIV-positive children on ART during three years of observation. Another study reported that CD4 and CD8 T cells were more activated in CMV seropositive HIV-positive children than in CMV-negative children. This difference in activation state disappeared once the children began ART. However, when compared to nonsecretors, children with prolonged CMV secretion in urine showed higher levels of CMV-specific IgG and more activated CMV-specific effector T cells, while CMV-specific IFN-γ-producing CD8 T-cell numbers were reduced. This may indicate an impairment in the ability to differentiate into functionally active effector cells and may explain the inability to completely suppress CMV.

Evaluation of antimycobacterial immune responses in children who had been previously vaccinated with BCG, and who had begun ART while having advanced disease, showed that initiation of ART was followed by a rapid and sustained recovery of specific responses against mycobacteria.

Studies on the reconstitution of NK and dendritic cells during ART in children demonstrated that while most NK subsets recovered on viral suppression, the level of the major subset of mature NK cells remained depressed. Plasmacytoid dendritic cell percentages in children recovered fully, in contrast to those in adults. However, other studies indicated that plasmacytoid cell numbers did not fully recover in children, despite full viral suppression. The functional capacity of plasmacytoid dendritic cells, as measured by their ability to produce interferon alpha, remained impaired in HIV-positive children on ART, irrespective of viral suppression. This may be one of the mechanisms explaining why a diminished response to antigens still occurs after immune reconstitution during ART.
SUMMARY

HIV infection affects essential components of the immune system and results in severe immunosuppression. In the majority of infants and young children, the ability to control HIV infection to some extent is clearly reduced when compared to adults and, as a result, HIV runs a rapid and devastating course in a significant proportion of untreated HIV-positive children. Similar to the process in adults, chronic activation of CD4 T cells appears to be a main factor contributing to the exhaustion and depletion of the CD4 T-cell pool.

The mechanisms behind the failure of the immune system to limit the HIV infection are only beginning to emerge. Immunologic responses have either been weaker or different from those observed in adults. On one hand, this may be explained by the immaturity of the immune system; on the other hand, recent findings indicate that HIV variants that already escaped cytotoxic actions of the genetically identical maternal immune system may be responsible for this phenomenon.

With progression of HIV infection, children develop deficiencies of both the humoral and cellular pillars of the immune system. Due to a continuous polyclonal activation of B cells, hypergammaglobulinemia develops, but specific antibody production deteriorates, as is reflected by a decreased capacity to respond to vaccination antigens and by a loss of protective antibody levels.

When interpreting CD4 values, physicians caring for HIV-positive children should keep in mind that basic CD4 T-cell numbers are physiologically higher in infants and change during childhood. Moreover, environmental factors such as a higher burden of parasitic infections appear to influence baseline levels of immunologic markers. This area requires further evaluation since the need for ART is determined on the basis of clinical symptoms and CD4 T-cell level.

Fortunately, the majority of children show a rapid clinical recovery and reconstitution of the CD4 T-cell pool in response to ART. However, it appears that even in children with a favorable clinical and virological response to ART and normalized CD4 levels, a functional impairment of the immune system is still present. Finally, because of the differences found between the immunologic responses in infants and adults, the exact mechanisms of the interaction between HIV and the infant’s immune system need to be unraveled to determine the value of novel immunotherapeutic strategies for improved control of HIV infection in children.

HE USE OF ANTIRETROVIRAL THERAPY (ART) in developed countries has successfully reduced AIDS-related mortality by 90% and has significantly reduced opportunistic infections and other consequences of HIV disease. In developing countries, combination ART has transformed the AIDS epidemic, with significant decreases in mortality, hospitalizations, and incidence of opportunistic infections. Yet in sub-Saharan Africa, which accounts for more than 70% of the global burden of HIV/AIDS, only about 25% of the six million people who require ART have access to treatment. This is despite continued calls to get more people on treatment, including initiatives such as the “3 by 5” campaign of the World Health Organization (WHO) and Joint United Nations Program on HIV/AIDS (UNAIDS), and the Group of Eight (G8) pledge to provide “universal access to ART.”

In order to ensure universal access to ART and ART-related services, particularly in resource-limited settings, WHO and UNAIDS have advocated and promoted a public-health approach to combating HIV/AIDS. The public-health approach operates at both the national and community level, and includes the simplification and standardization of protocols and decentralization of comprehensive HIV services, while taking into account the realities of weak health-care systems and the experiences of pioneering ART programs. The key components of this approach include (1) standardization and simplification of regimens to ensure efficient and durable suppression of HIV, (2) ensuring equitable and standardized treatment that is accessible to all in need of ART, and (3) use of cost-effective combinations of antiretrovirals (ARVs) in the form of generics. This shift from an individual to a population-based approach is facilitating rapid access to ART and related services for millions of people. Other benefits of the public-health approach include the streamlining of education, training, and administration related to the provision of ART. Simplification and standardization of ARV drug combinations means that with adequate training, nurses and clinical officers (COs) can deliver ART in countries where there is a shortage of doctors. In addition, prospects for drug tolerability and adherence to ART are enhanced, as health-care workers need only be familiar with a few types of drugs.
BASIS PRINCIPLES AND OBJECTIVES OF ART

The treatment and care of people living with HIV requires the comprehensive integration of patient-centered medical and social services. These services include provision of clinical care, nursing care, nutritional care and support, psychological support, health information and counseling, legal protection, and economic assistance. Comprehensive clinical care for people living with HIV, one vital component of this group of services, includes early diagnosis, access to care, ART, palliative care, prophylaxis against opportunistic infections, treatment of opportunistic infections and malignancies, and end-of-life care. The provision of this wide spectrum of services requires multisectoral and multidisciplinary teams that are cross-linked in a continuum-of-care model, so that patients, their families, health-care providers, governmental and nongovernmental organizations, and the community are closely involved with and knowledgeable about all aspects of care.

Prevention of new infections should be integrated into HIV/AIDS treatment and care programs as well, as HIV remains an incurable infection despite advances in ARV treatment. Toward this end, “social immunization” (for example, through community mobilization, widespread education, counseling and testing, sexual abstinence until marriage, being faithful, use of condoms, and female empowerment) must be strengthened, as we await the development of effective vaginal microbicides, HIV vaccines, and other prevention strategies currently under investigation. On one hand, even if HIV transmission in resource-limited countries were to totally cease, the existing burden of HIV/AIDS would continue to task all stakeholders into the foreseeable future. On the other hand, a lack of adequate preventive measures would mean longer queues of people waiting to access ART, which would compound the present challenges in achieving universal access.

The main goals of ART remain to (1) clinically prevent disease progression, (2) improve the restoration of the body’s immunity, (3) control viral replication through durable suppression, and (4) possibly reduce individual infectivity. However, this must be done in the context of an optimal quality of life by ensuring that drugs are available, tolerable, and easy to administer; have little long-term toxicity; and involve no food or refrigeration restrictions. Despite their immense benefit to people living with HIV, ARVs are not without risks, including drug toxicity and viral resistance. Experience with combination ART in the last decade has taught providers the central role of informed patient participation, the need for meticulous medication adherence, the complexity of drug interactions, and the importance of regular monitoring.6

ASSESSING PATIENT READINESS

Guidelines for ART determine when patients are eligible to begin treatment. In order for treatment to be successful, patients must also be ready to take medications every day for the rest of their lives. In most cases, this requires adequate preparation and a significant amount of patient support before ART is initiated. There is no substitute for patient participation in the ART decision-making process, and patient education and adherence programs should be part of any HIV/AIDS care initiative. Patients need to be asked whether they are ready to start a lifetime of therapy and should only commence taking drugs when they are fully committed to this responsibility. Some patients may not be ready right away. In such cases, individuals can be scheduled for follow-up visits with adequate pretreatment counseling until they are ready to begin treatment.
MINIMIZING VIRAL RESISTANCE

Providers in resource-limited settings have important roles to play in delaying the occurrence of HIV resistance. This can be achieved through good patient adherence and responsible, well-informed prescribing practices. Recommended strategies to achieve these goals include the following:

- Never commence patients on ART in the absence of adequate adherence counseling and support. The use of family and community members (spouses, buddies, etc.) has been found to be invaluable as a form of treatment support. Similarly, ensuring that disclosure to family members has been observed will enhance adherence and positive living.
- Work with patients to minimize barriers to medication adherence.
- Use fixed-dose combinations or co-blister packs.
- Pay special attention to other medications and treatments and their potential interactions with ARVs (particularly anti-TB drugs) and other drugs taken for concomitant illnesses, including traditional medicines.
- Never prescribe monotherapy or dual therapy for treatment of chronic HIV infection.
- Never add or change a single drug in a failing regimen, as this would result in functional monotherapy or dual therapy.
- If there is a reason to stop treatment, such as serious side effects or lack of adherence, it is recommended that the non-nucleoside reverse transcriptase inhibitors (NNRTIs) be stopped first (because of their long plasma half-life) and the nucleoside reverse transcriptase inhibitors (NRTIs) only after several days, to minimize NNRTI resistance.

STEPS TO INITIATE ART

The following steps should be taken in initiating ART:

1. HIV pretest counseling
2. HIV testing using the WHO-recommended algorithm (with Enzyme-Linked Immuno-Sorbent Assay [ELISA] or rapid tests) or national guidelines (where available) and post-test counseling
3. Medical consultation:
   - Medical history, which should include previous history of ART exposure, any concomitant treatment for other conditions, and substance/drug abuse
   - Clinical examination, including clinical WHO staging and weight measurement
   - Screening for TB (pulmonary and extrapulmonary)
   - Biochemical and hematology tests, including complete blood counts, urea and creatinine, electrolytes, liver function tests, and serum lipids including triglycerides
   - Tests for other opportunistic infections/diseases, including hepatitis B virus (HBV), hepatitis C virus (HCV), sexually transmitted infections (STIs), and malaria
   - CD4 lymphocyte count and viral load (where available)
   - Pap smear (for women)
   - Pregnancy test (for women of childbearing age)
4. Patient follow-up:
   - Review of test results
   - Staging of disease and determination of eligibility for ART, including psychosocial considerations of active alcohol/substance abuse, depression, and disclosure
• Counseling and review of treatment options—treatment literacy counseling should be routine for all HIV-positive patients, and those requiring ART should receive treatment literacy and drug adherence counseling
• Cotrimoxazole prophylaxis for patients with CD4 counts less than 350 cells/mm³, as this protects them from diarrhea, respiratory infections, and malaria
• A socioeconomic assessment of the patient to determine adequacy of food supply and other potential barriers to adherence

5. Patient monitoring:
• Choosing the optimal ARV drug regimen and explaining it in detail to the patient
• Providing ART and organizing drug counseling for maximum adherence
• Providing ongoing counseling, including advice on safer sex and family planning
• Monitoring ART in the following areas:
  – Clinically—watching for weight changes, frequency/severity of opportunistic infections
  – Biologically—CD4 cell count, viral load, and resistance
  – Adherence
  – Adverse events

A physician or CO should be responsible for conducting the initial clinical history and physical examination in a secondary or tertiary health facility. This step is important, as this initial evaluation also assesses the patient for opportunistic infections, such as TB, and comorbidities that have been observed to lead to significant mortality at the onset of treatment or that can cause toxicities to ARV drugs. The physician or CO should assess the WHO staging of each patient and design a care and treatment plan for the patient during this initial assessment. It is the responsibility of the physician or CO to request any required lab tests and prescribe necessary medications for patients. In addition, the physician or CO will monitor the patient on an ongoing basis using clinical criteria and CD4 counts in addition to viral loads, where available. For patients already receiving ARVs, any side effects will be monitored and patients will be assessed for treatment failure based on clinical signs, CD4 counts, and viral loads.

The initial evaluation should also educate the patient about the need for a treatment partner or “buddy” to enhance adherence to ART. This is best done by an adherence nurse or adherence counselor, who will counsel patients on adherence for routine care and ARV treatment, and encourage personal risk reduction. Many ART clinics in resource-limited settings employ people living with HIV as adherence nurses/counselors, which can be a more effective way of getting patients to adhere to their drugs. Oftentimes it is easier for patients to trust the advice of those who are in a similar situation to their own, rather than the advice of a clinician. Support group members can be trained as peer educators/counselors for adherence counseling of their peers in the clinic and within the community. In addition, the adherence nurse/counselor will assess the need for nutritional support in those clinics where a qualified nutritionist is unavailable.

Most ART scale-up models in resource-limited settings have adopted a network model, which consists of clusters of primary health clinics (PHCs) feeding secondary health centers. In this model, secondary centers in a region or zone of the country develop referral linkages to a tertiary or referral center. This allows for vertical and horizontal referral of patients, with monitoring and mentoring cascading down from the referral center and district centers to the PHCs. In countries with reasonable human resources, ART is delivered at the tertiary and secondary (district) health facilities, with PHCs delivering ART-related services such as
Voluntary counseling and testing (VCT), prevention of mother-to-child transmission (PMTCT), STI treatment and prevention, and directly observed therapy short course (DOTS) for TB. In addition, PHCs can deliver food supplements, cotrimoxazole prophylaxis, and basic care kits (e.g., clean water, water guard, and bed nets).

Because of the chronic shortages of health staff in sub-Saharan Africa and elsewhere, nurses in many countries are being called upon to deliver comprehensive ART, including the dispensing of ARVs at district and community health facilities. Offering ART at the community level reduces transportation time and costs, as well as patient loss to follow-up. In countries employing such a model, there has been a gradual transition from a doctor-driven to a nurse-driven ART program. This shift has enhanced treatment equity by making ART available to a wider population, including those in rural areas. However, in order for such a model to work, it is critical to develop guidelines and standard operating procedures (SOPs) for the various cadres of staff involved in the program, including clinicians, nurses, pharmacists, laboratory staff, and data managers. Also critical are tools for referrals of patients to and from PHCs and district, regional, and/or tertiary care facilities, in order to guide health-care providers in proper patient management at the various levels of care.

In a decentralized model, community-level facilities (PHCs) are responsible for identifying HIV-positive patients through HIV counseling and testing (HCT) at all entry points, including VCT, PMTCT, TB, STI, Integrated Management of Childhood Illnesses (IMCI), Expanded Program on Immunization (EPI), and family planning. Community-level facilities are also responsible for preparing ART-eligible patients for up referral to the secondary or tertiary centers for initiation of ART. This will rapidly expand the pool of HIV-positive individuals who can access ART. By the same token, PHCs can receive and manage stable down-referred patients already receiving ART. To guarantee quality care, such schemes require intense capacity building of various cadres of staff and the development of referral tools, protocols, and guidelines. Integration of ART services with other PHC-based services, such as malaria treatment, facilitates patient identification through HCT. This allows for eligible adults and pregnant women to be speedily referred to the ART initiation center (i.e., a center where HIV-positive individuals are initially assessed and commenced on ART). HIV-exposed children less than 18 months of age are polymerase chain reaction (PCR) tested and positive cases referred early for treatment, while older children can be diagnosed using rapid tests and ELISA. The offering of comprehensive services, such as HCT, PMTCT, and ART, promotes a family-centered approach. Expanding HCT at the PHC level also provides expanded access to counseling for HIV-negative clients, to ensure that they protect themselves from infection.

**WHEN TO START ART**

A patient should meet the following clinical and social criteria in order for ART to be initiated:

1a. Clinical criteria where CD4 testing is available:
   - WHO clinical stage IV disease irrespective of CD4 cell counts
   - WHO stage III disease + CD4 cell count < 350 cells/mm³
   - WHO stage I or II disease + CD4 cell count < 200 cells/mm³

1b. Clinical criteria where CD4 testing is not available:
   - WHO stage II if total lymphocyte count is ≤1,200 cells/mm³
   - WHO stage III irrespective of total lymphocyte count
   - WHO stage IV irrespective of total lymphocyte count
FROM THE GROUND UP: ESTABLISHING A FRAMEWORK FOR SUCCESS

1c. Clinical criteria for adults coinfected with TB and HIV:
- CD4 <200 cells/mm³—Start TB treatment. Commence ART in two to eight weeks.
- CD4 200–350 cells/mm³—Start TB treatment. Commence ART after initiation phase or earlier with severe immunodeficiency.
- CD4 >350 cells/mm³—Start TB treatment. Defer ART.
- Extrapulmonary TB—ART should be started as soon as anti-TB treatment is tolerated.

2. Social criteria:
- The patient should be willing to visit the health facility regularly and be contacted anytime at home or elsewhere.
- Although it is not mandatory, patients should be encouraged to disclose their HIV-positive status to a family member or a close friend who will accompany the patient for adherence counseling sessions and support the patient’s medication adherence after starting ART.
- Living in the same locality as the clinic or not too far away enhances adherence to clinic follow-up visits and tracing by caregivers in cases of default.

Before therapy is initiated, patient education and preparation is essential to ensure that the patient understands the way ART works, as well as to assess his or her willingness to make a lifelong commitment to therapy. In adults, the decision of when to start ART and with what regimen is complicated by other prevailing factors, such as pregnancy, the presence of comorbidities (e.g., TB, hepatitis B or C), uninfected partners, anemia, and the availability and cost of the drugs. A successful ART regimen must take these factors into consideration.

The optimal time to initiate ART in adults living with HIV has remained one of the most controversial and hotly debated topics in HIV medicine. Commencing ART prematurely may lead to unnecessary side effects or early development of drug resistance, whereas starting late may lead to reduced therapeutic benefits and high mortality. The lack of randomized trials demonstrating the optimal time to start therapy has forced such decisions to be based on expert recommendations and consensus guidelines. Most guidelines in resource-limited settings have previously recommended initiating therapy in patients with WHO stage III or IV disease and others with CD4 cell counts of less than 200 cells/mm³. However, many countries have reviewed their guidelines in light of recent evidence and WHO recommendations for resource-limited settings that suggest treatment be considered for individuals with CD4 cell counts between 200 and 350 cells/mm³. The move toward earlier treatment initiation is related to recent evidence showing that earlier initiation is associated with quicker normalization of CD4 cell counts, with a longer-term benefit to patients. Recent cohort studies have demonstrated benefits associated with starting therapy at CD4 cell counts between 250 and 350 cells/mm³, and new WHO guidelines favor moving the bar upward. In addition, newer drug formulations are more convenient and better tolerated, have fewer side effects, and demonstrate better durability.

WHAT TO START: CHOOSING THE BEST COMBINATION ART REGIMEN
The first component of the public-health approach to HIV medicine has been the simplification and standardization of first- and second-line drug combinations. There are currently five main classes of ARV agents available: the three classes used widely in resource-limited settings, NRTIs, NNRTIs, and protease inhibitors (PIs), and the two newer classes, entry inhibitors and integrase inhibitors. In adopting a public-health approach, a triple-drug regimen is constructed...
Most ART programs in resource-limited settings use NNRTI-based regimens because they have reliable pharmacokinetic properties, are effective at high viral loads / low CD4 counts (many patients present at this stage in such settings), and allow the sparing of PIs, which can be reserved for second-line and salvage therapy. The NNRTI efavirenz (EFV) remains the “standard of care” based on reports from several clinical trials.17,18 While some experts have observed that nevirapine (NVP) was comparable to EFV in the 2NN study, others have interpreted the 2NN data as showing nevirapine’s inferiority.19 Regardless, this class of drugs has a low genetic barrier to resistance and suffers from extensive cross-resistance.20 In addition, mutations archived from the use of single-dose nevirapine (sdNVP) for PMTCT have been observed to negatively impact the effectiveness of subsequent ART combinations containing nevirapine.21 However, a recent study from South Africa assessing the efficacy of NNRTI-based regimens in women who had previously received single-dose nevirapine for PMTCT, in comparison to the efficacy in women who had not received single-dose nevirapine, found that if combination ART was initiated after 18 months of single-dose nevirapine, there was no difference in early virologic response through 24 weeks.22

Nevirapine can cause serious hepatic toxicities and skin reactions in patients with high CD4 counts23 and others coinfected with HBV or HCV.24 The risk of potentially fatal nevirapine hepatotoxicity, which can occur in the first six weeks of therapy, appears greatest in women with a CD4 count greater than 250 cells/mm³ and in men with a CD4 count greater than 400 cells/mm³.25 For this reason, nevirapine is contraindicated in these individuals. EFV can lead to serious central nervous system (CNS) side effects in 5% to 10% of patients in the first few weeks of treatment and is contraindicated in women of childbearing age in developing countries.
countries because of teratogenicity (i.e., potential ability to cause birth defects).

Triple NRTI-based regimens are simple to use, have a low pill burden, are well tolerated, and allow the sparing of PIs and NNRTIs. However, these regimens are less potent than other currently used regimens. Zidovudine toxicity may also pose a problem in many resource-limited settings, as patients presenting for ART often have marginal hemoglobin levels. However, there have been promising preliminary results from the DAART trial for the triple combination of tenofovir, zidovudine, and lamivudine (3TC).27

New First-Line Antiretroviral Combinations

New ARV combinations include the following:

- TDF + FTC + NVP
- TDF + FTC + EFV

Tenofovir, a nucleotide reverse transcriptase inhibitor (NtRTI), has proven very useful, particularly since it is effective and safe and may not share similar resistance mutations with thymidine analogues. Tenofovir, plus either lamivudine or emtricitabine (FTC), has been shown to be well tolerated and as effective as stavudine plus lamivudine.28 To date, it appears that long-term toxicities such as lipoatrophy and hypertriglyceridemia are lessened with the use of tenofovir as compared with stavudine-based treatment. By the same token, tenofovir is an alternative option for patients, and, as shown by Gallant et al,29 tenofovir-based regimens are now considered better than zidovudine-based regimens.

The coformulation of tenofovir plus emtricitabine (brand name Truvada) allows this combination to be taken as a once-daily regimen with efavirenz, requiring only two pills per day. Recently another coformulation of three drugs (TDF + FTC + EFV) under the brand name Atripla has been introduced onto the market. This combination is available as one single pill taken daily. However, two tenofovir-based combinations have recently shown high rates of virological failure. These include abacavir + lamivudine + tenofovir30 and didanosine + lamivudine + tenofovir.31 Tenofovir is very active against HBV and therefore is highly recommended in patients with coinfection of HIV with HBV.32 However, tenofovir has been linked with acute and chronic renal insufficiency, particularly in individuals with occult renal disease,33 and bone demineralization.34

Second-Line Therapy

Recommendations for second-line therapy include the following:

- Failed first-line AZT combination: switch to TDF + 3TC or FTC + LPVr
- Failed first-line TDF combination: switch to AZT + 3TC + LPVr

Boosted PI regimens are the backbones for most second-line and salvage regimens in the majority of resource-limited settings. Ritonavir-boosted lopinavir (LPVr), in particular, has demonstrated potency in multiple clinical trials.35 Findings from several studies have noted a high genetic barrier to resistance and efficacy in patients with high viral load and low CD4 counts taking boosted lopinavir.36 Although lamivudine loses its direct virologic potency in the presence of the M184V mutation, it may be retained in the regimen (as a third NRTI) because it allows for the persistence of M184V mutants that replicate poorly due to reduced viral fitness.37 The use of lamivudine or emtricitabine also remains helpful, as it may lead to hypersusceptibility to certain other NRTIs, such as tenofovir.38 Similarly, even when there is evidence of thymidine-analog mutations (TAMs), the addition of zidovudine to a tenofovir-containing second-line drug combination may enhance the efficacy
of the regimen. A plausible explanation for this has come from a recent study that observed that K65R mutation inhibits the excision of nucleotides from the growing DNA chain, thereby increasing the efficacy of zidovudine.

Third-Line or Salvage Therapy
Patients who fail second-line therapy will eventually need salvage or third-line treatment, which is complicated and costly. With the availability of more effective drugs, the goal of all therapy is to reduce the viral load to less than 50 copies/mL. To achieve durable virologic suppression, it is recommended that a minimum of two new drugs be used, ideally each from a new class of drugs. The development of new agents is the best hope for patients with multi-class resistance. These include “second-generation” agents in existing classes with unique profiles such as tripranavir (TPV), darunavir (TMC-114), and etravirine (TMC-125). Other agents come from novel classes with novel mechanisms of action to which there is no cross-resistance, such as raltegravir (MK-0518), an integrase inhibitor, and maraviroc, an entry inhibitor. It is important to note that two boosted PIs act as one drug, or monotherapy, and their use for salvage therapy should be discouraged. If no new drugs are available, it is recommended that the patient continue on current treatment until new drugs become available.

MONITORING PATIENTS ON ART
Prior to initiating therapy, the clinician and patient must agree on a schedule for monitoring the progress and effects of therapy. Following patients on ART is a lifelong activity. At a minimum, patients who are stable should be evaluated at the clinic every three months by the clinician and have a laboratory assessment twice annually (see Table 1). Monitoring should be more frequent at treatment initiation, at the time of any treatment change, or in the case of concurrent illnesses. Prior to selecting the ARV treatment regimen, patients will need to undergo a comprehensive clinical and laboratory evaluation, as outlined above.

A major obstacle to the effective use of ART has been a lack of agreement about how to monitor patients receiving ART and how to detect treatment failure. Plasma HIV-1 RNA (viral load) measurement remains the gold standard for monitoring patients in developed countries, but this test is considered too expensive or logistically difficult in many settings. Colebunders et al recently developed an algorithm for monitoring patients receiving ART in resource-limited settings that uses clinical and immunological indicators, including adherence, to assess treatment failure. A limited report from South Africa observed that despite some improvement in sensitivity for detecting virological failure compared with existing WHO criteria, the low sensitivity and specificity of the algorithm rendered it unusable as a substitute for virological monitoring. However, as suggested by Colebunders et al, less stringent models like this can be used as a screening tool for patients at risk of treatment failure who would then be candidates for targeted viral load testing. Without access to viral load testing, diagnosis of virological failure will be delayed. Therefore, although the search for other surrogate markers for treatment failure should be encouraged, there is an urgent need for the development of simpler and more cost-effective viral load assays.

The standard of care in many African countries has relied on the clinical assessment and clinical monitoring of patients. In such settings, CD4 cell counts and viral loads are often not measured, resulting in patients with low CD4 counts (less than 200 cells/mm³) not being considered for treatment because they may not have symptoms. This can lead to viral resistance and subsequent severe immune dysfunction being identified at a later stage, thus compromising any potential benefits from second-line ART. Some experts argue that monitoring ART in any setting will require CD4
and prepare samples that can be up referred to the regional center for viral load assays and PCR infant diagnosis. Community-level facilities should have the capacity to perform rapid tests for HIV serology, blood counts to identify anemia, and simple microscopy to diagnose TB and opportunistic diseases. One key element of a tiered laboratory program is the setting of national training standards for technicians/supervisors, test performers, and community health-care workers. In addition, the program should have quality assurance with a national or state/district quality assurance package incorporating proficiency testing and observed performance. The various laboratory assays should be guided by SoPs.

**Where available**

cell enumeration and plasma viral load determination, as plasma viral load is correlated with disease progression and is a critical parameter for assessing virologic failure. In tertiary and referral centers that have the necessary infrastructure and trained personnel to perform this assay, viral load determinations will provide the clinician and patient with critical information on the patient’s virological status during ART and will indicate when virologic failure has occurred. At points of care outside the referral center, where this assay is not available (such as at the district level), CD4 cell enumeration and clinical monitoring can be substituted. Other important monitoring tests that can be performed at district facilities include a sputum smear for TB, blood chemistry, serology for syphilis, HBV, HCV, and the hemoglobin or packed cell volume.

Laboratory services must be tiered if they are to function optimally during the scale-up to universal ART access. Regional or tertiary centers should have the capacity to perform all routine tests and be equipped to perform more sophisticated tests, including CD4 cell counts, viral load assays, PCR infant diagnosis, and, in rare cases, resistance genotyping. District-level laboratories should have the capacity to perform CD4 cell counts, carry out blood chemistry tests and counts, and prepare samples that can be up referred to the regional center for viral load assays and PCR infant diagnosis. Community-level facilities should have the capacity to perform rapid tests for HIV serology, blood counts to identify anemia, and simple microscopy to diagnose TB and opportunistic diseases. One key element of a tiered laboratory program is the setting of national training standards for technicians/supervisors, test performers, and community health-care workers. In addition, the program should have quality assurance with a national or state/district quality assurance package incorporating proficiency testing and observed performance. The various laboratory assays should be guided by SoPs.

**DETERMINING WHEN TREATMENT HAS SUCCEEDED OR FAILED**

Successful ART implies that a patient has taken his or her drugs and responded to treatment. Treatment failure is defined as an inadequate response to treatment for any of a variety of reasons. Clinical failure indicates progression of clinical symptoms or the emergence of new opportunistic infections, conditions, or death while on ART. Virological failure indicates the loss of control of viral replication. A successful response is associated with a rapid
decline in plasma HIV RNA and a corresponding increase in the CD4 cell count. Within 12 weeks of starting therapy, approximately 80% of patients will have HIV RNA of less than 400 copies/mL and a CD4 count increased by approximately 50 cells/mm³. The maximum effect of treatment should be observed in the majority of patients by 24 weeks. Over 95% should have plasma HIV RNA below 400 or 500 copies/mL and a CD4 count increased by 50 to 100 cells/mm³.

There is greater variability in the change in CD4 count as compared to HIV RNA, especially early on in treatment. Of note, approximately 10% of patients have a disconnect between response in HIV RNA and CD4 cell counts, meaning that HIV RNA declines, but the CD4 count increase is blunted. Such patients should be allowed to continue with their ARV combination. Factors associated with such reduced CD4 cell response include older age, a lower baseline CD4 cell count, and a very low nadir CD4 cell count. TB, and to a lesser extent malaria infection, has been associated with decreased CD4 cell counts. These coinfected patients require continued prophylaxis with cotrimoxazole for opportunistic infections if their CD4 cell count is below 350 cells/mm³. If the plasma HIV RNA does not decrease steadily over the first three months of treatment, or it rebounds to within 0.5 log₁₀ copies/mL of pre-therapy values, then the ART regimen is failing. By 24 weeks, if the HIV RNA has not decreased to a level below detection (less than 400 copies/mL), the patient should be considered as having failed therapy (i.e., virologic failure). Similarly, if (a) the CD4 cell count remains below 100 cells/mm³ after six months of treatment, (b) there is a return to or a fall below the pretreatment CD4 baseline after six months of treatment, or (c) there is a 50% decline from the on-treatment peak CD4 value, the patient should be considered as having immunological failure. The development of a new or recurrent WHO stage III or IV condition after six months is considered evidence of disease progression and therefore indicates treatment failure on a clinical basis.

In addition to the laboratory changes in HIV markers described above, patients during the first few months of therapy should feel better clinically if they were symptomatic prior to therapy. Patients typically describe an improved sense of well-being, weight gain, and less fatigue. They may note a decrease in oral or vaginal candidiasis, fewer herpes simplex outbreaks, improvement in skin and/or hair texture, regression of condylomata, and regression of Kaposi’s sarcoma. Serum cholesterol levels may increase and triglyceride levels decrease, corresponding to a return to pre-HIV infection status. However, it should be noted that some patients, especially those with severe immunosuppression at baseline, may develop immune reconstitution inflammatory syndrome (IRIS), where some lesions, including herpes simplex virus, condylomata, and even Kaposi’s sarcoma may get worse with commencement of ART (see chapter entitled “Immune Reconstitution Inflammatory Syndrome” for more information).

CONCLUSION

Current evidence indicates that starting therapy at CD4 cell counts of 200 cells/mm³ or below is too late. We must increase this threshold in light of evidence that patients do better when started on ART at a higher threshold now that we have new, more effective, less toxic, and more convenient drugs at our disposal. Combination ART should be commenced based on the degree of immunosuppression, using symptoms and CD4 cell counts as recommended by the WHO guidelines for scaling up ART in resource-limited settings. Patients should commence ART only when they have received enough education to understand what HIV is, as well as how the treatment works and what various treatment options exist. The importance of
adherence should be stressed, and, as much as possible, the use of treatment support partners should be encouraged to facilitate adherence to ART. Patients should be motivated and deemed “ready to start” ART before they commence treatment. Additionally, ART must be provided as a comprehensive package, consisting not only of ARVs but of regular counseling, psychological support, prophylaxis for and treatment of opportunistic infections, and nutritional support.

Most of the currently recommended ART regimens are effective. However, triple NRTIs are less effective than some other regimens. Regimens are differentiated by related complications, pill burden, tolerability, toxicity, monitoring requirements, potency, drug interactions, refrigeration requirements, suitability for use during pregnancy, and possible effects on comorbid conditions. The choice of regimens should be based on considerations of potency, tolerability, convenience, long-term toxicity, and drug resistance. Because of the long-term complications of lipodystrophy and peripheral neuropathy, stavudine-based regimens should be discouraged. Zidovudine- and tenofovir-based regimens are the preferred options, while boosted PIs should be reserved for second-line therapy. However, it remains to be seen whether the survival outcomes associated with this strategy in resource-limited settings are comparable to those associated with a combination of PIs and NRTIs. The goal of treatment for both first- and second-line treatment is the achievement of an undetectable viral load, a progressive rise in the CD4 cell count, and a decline in the frequency and severity of opportunistic infections using a public-health approach. Therefore, any progress short of these milestones may be associated with decreased durability and portend the development of drug resistance.

Task shifting from physicians to nurses and COs allows nurses and COs to assume broader clinical duties and provide leadership for the HIV care team, thereby freeing up physicians to treat more patients. However, more evidence is needed on how ART programs managed by nurses and COs compare to physician-led care in terms of individual and community-based outcomes. Community involvement through education, preparedness, support activities, and mobilization can greatly enhance drug adherence and reduce stigma and discrimination, which are major obstacles to ART access.

Finally, the strategy that may prove most useful for the massive scaling up of ART programs in resource-limited settings is one that employs a community-based approach and that provides ART services at no cost to the patients through a tiered delivery model, while preserving the quality of care. This strategy allows for the delivery of ART at zonal/regional centers of excellence (i.e., tertiary centers), at state/district facilities (i.e., secondary centers) that meet minimum requirements for ART, and at community-based facilities (PHCs) that do not meet the minimum requirements for ART but can provide care and support services, including VCT and referrals.

Antiretroviral Treatment Failure, Drug Resistance, and Management of Therapy-Experienced Patients

Babafemi Taiwo and Robert Murphy

Northwestern University Feinberg School of Medicine, Division of Infectious Diseases, United States.

MOST FIRST-LINE ANTIRETROVIRAL therapy (ART) in resource-limited settings comprises a non-nucleoside reverse transcriptase inhibitor (NNRTI) plus two nucleos(t)ide reverse transcriptase inhibitors (NRTIs), or a combination of three NRTIs. Several treatment programs in such settings have recorded good adherence rates as well as virologic, immunologic, and clinical success comparable to what exists in industrialized countries; however, overall treatment capacity (trained personnel, available drugs, and infrastructural support) falls far short of the need. Many patients receive care from ART-inexperienced practitioners and clinics, where they may be prescribed nonsuppressive ART or unproven herbal remedies, in addition to suboptimal or inadequate follow-up and support. Furthermore, the use of single- or dual-agent ART for the prevention of mother-to-child transmission (PMTCT) is widespread. Cultural barriers including stigmatization and discrimination are frequently cited as additional impediments to adherence and viral suppression and, hence, as indirect promoters of resistance. Despite these issues, assumptions that antiretroviral resistance will inevitably be worse in resource-limited settings than in industrialized countries are unsubstantiated. The fear of resistance, therefore, should not constitute a barrier to treatment.

Some degree of resistance will emerge in all settings where ART is delivered: for example, rates of resistance in industrialized countries have been estimated at 27% by six years in patients starting on three or more drugs. By the same token, some patients in resource-limited settings will fail first-line ART or do poorly after being exposed to nonsuppressive regimens. This failure is often a reflection of resistance mediated by incomplete viral suppression and suboptimal adherence. Also, transmitted resistance is an emerging problem, although the scale is not well defined. Overall, a cumulative increase is expected in the number of patients who need second-line therapy or deeper salvage, but this can be lessened if maximum adherence and complete viral suppression are entrenched as the cornerstones of ART at individual and programmatic levels.

RESISTANCE

Human immunodeficiency virus (HIV) replication is an imperfect and error-prone process with frequent alterations in viral amino acid sequence
mutations) from wild-type (drug-sensitive) virus. Approximately one mutation occurs with every replication cycle, which translates into several billion mutations per day. Given this rapid turnover, each untreated person harbors a swarm, or quasispecies, of genetically related but distinguishable HIV strains, including some with “incidental” resistance mutations. In the absence of ART, such incidental mutations are temporary and nondominant for a simple reason: in order to maximize its chances of survival, the virus, like other pathogenic organisms, evolves toward the strains that are fittest for that particular environment. Thus, in the absence of ART, highly replicative wild-type virus is dominant. Conversely, when a patient is receiving ART, viral evolution favors strains that are best able to replicate in that environment, which tend to be the strains that are resistant to current ART. In summary, HIV resistance results from a dynamic interplay of (1) HIV diversity; (2) HIV replication; and (3) selection pressure exerted by ART. The most likely scenario for these three factors to coexist is when there is high-level viremia and poor adherence to ART. In contrast, while cryptic replication may persist in some cellular compartments of adherent patients who are aviremic (no detectable plasma virus), resistance is unlikely to develop. Also, new durable resistance is unlikely to develop in the absence of ART.

**PRIMARY VERSUS SECONDARY RESISTANCE**

HIV resistance can be classified as primary (transmitted) or secondary. Primary resistance is acquired from the index patient at the time of initial infection or reinfection (superinfection). It is important to distinguish resistance mutations from naturally occurring polymorphisms on protease and reverse transcriptase that may influence the emergence of resistance. Primary resistance is now reported in approximately 10% of newly infected patients in industrialized countries where ART has been in use for more than 10 years. Definitive data are scarce from resource-limited settings with limited ART experience, although it is likely to be comparatively low for now. Primary resistance may persist for several years in plasma or semen, and early virologic failure in patients receiving combination ART is sometimes traceable to resistance to a single component of the regimen. As the impact of primary resistance on HIV epidemiology and management in resource-limited settings plays out over the next decade, the preliminary report of a panel of experts convened by the World Health Organization (WHO) in 2003 is a good reference point for countries contemplating the relevance and logistics of resistance surveillance in their population. Some of the key recommendations were that resistance surveillance should (1) be conducted when ART programs are well established and have sufficient coverage, or when drug resistance may be greater than 5%; (2) focus on treatment-naive persons, with a preference for those who are recently infected; (3) focus on testing and counseling centers such as antenatal clinics; and (4) sample approximately 500 patients per site, which is sufficient to capture a change in resistance from 5% to 10%.

Secondary resistance refers to resistance that develops while the patient is receiving ART. This is thought to be the more common form of resistance at this time in resource-limited settings, and it is closely linked to incomplete viral suppression while on ART. The experience from Thailand, where increased prevalence of resistance was seen with expanded ART, buttresses the need for resistance surveillance in national ART programs. Apart from the potential adverse effects on clinical course and response to ART, patients with secondary resistance serve as reservoirs of the strains that result in primary resistance if transmitted to new persons. Unlike primary resistance that often remains detectable in plasma for long periods in
the absence of ART, secondarily developed resistance is typically rapidly replaced by wild-type if ART is withdrawn. The time for such “reversion” to wild-type may be as short as a few weeks.15

Even when resistance mutations become undetectable in plasma, they may be archived in proviral DNA and can repopulate plasma if the drug (or a similar drug) to which resistance was developed is reintroduced.16 An illustrative scenario is seen among patients with secondary resistance to efavirenz or nevirapine. If the NNRTI is discontinued, circulating viruses will likely change from NNRTI mutants to wild-type. However, the NNRTI-resistant strains will likely reemerge if the patient is reexposed to efavirenz or nevirapine.

**HIV DIVERSITY AND RESISTANCE**

Circulating HIV strains around the globe are diverse and complex17 with the main (M) type being predominant. Subtype C viruses, the most common subtype in South and East Africa as well as India, are the most prevalent worldwide. Subtype A is commonly found in East Africa, subtype B in North America, Europe, and Australia, and subtype D in East Africa. There are several circulating recombinant forms (CRFs) including CRF02_AG, which is common in West Africa. Groups O and N are mainly found in Cameroon, while HIV-2 is largely confined to West Africa. It is common for multiple subtypes to coexist in the same population. Most available data on ART resistance were derived from the B subtype.

While it remains uncertain what intrinsic differences, if any, exist in preferred resistance pathways or durability of selected mutations among different HIV subtypes, several preliminary observations testify to this potential. For example, polymorphisms have been demonstrated in non-B subtype HIV at protease and reverse transcriptase sites known to be associated with resistance.18,19 Theoretically, some of these polymorphisms may alter the steps to clinically significant mutations, or lead to novel pathways of mutational escape under drug pressure. This is illustrated by D30N, which is a common mutational pathway to high-grade nelfinavir resistance in subtype B patients, but is uncommon with non-B subtypes, probably because of existing polymorphisms.20 Also, the K103N mutation in recipients of single-dose nevirapine (sdNVP) tends to persist longer among those infected with HIV subtype D versus subtype A.21 For now, clinical practice in resource-limited settings is driven by the evidence of overlap in mutational pathways,22 and responses to ART among B and most non-B HIV subtypes. Differences likely exist, however, such as the suggestion that subtype G may be less susceptible to protease inhibitors (PIs).23,24 Clearly, research focusing on the relationships between the non-B HIV subtypes and HIV resistance is needed.

**OVERVIEW OF SELECTED MUTATIONS**

**M184V and M184I**

The M184I mutation is often the first to emerge during lamivudine or emtricitabine exposure; however, it has lower replicative capacity than M184V, which becomes the dominant mutation.25 M184V potently blocks the incorporation of lamivudine and emtricitabine into viral DNA chain, inducing high-level (up to > 500-fold) resistance to those drugs, and lower (often clinically insignificant) resistance to didanosine, zalcitabine, and abacavir.26 On the other hand, it causes increased susceptibility to zidovudine, stavudine, and tenofovir because it counteracts their excision from viral DNA.27,28 Strains with M184V have significantly reduced replicative capacity that may be beneficial clinically.29 Despite the low genetic barrier to resistance, lamivudine and emtricitabine are cornerstones of ART worldwide.
Thymidine-Associated Mutations

The thymidine-associated mutations, or TAMs (M41L, D67N, K70R, L210W, T215Y/F, and K219E/Q), are selected by zidovudine or stavudine, two commonly prescribed NRTIs in resource-limited settings. They tend to accumulate in patients who are left on a failing regimen with ongoing viral replication, typically in one of two clusters: M41L, L210W, and T215Y, leading to more-extensive cross-resistance to NRTIs, or D67N, K70R, T215F, and K219E/Q, leading to less-extensive cross-resistance. TAMs reduce viral susceptibility to many NRTIs, especially zidovudine and stavudine. However, single TAMs generally cause only relatively low-level resistance, which may not significantly compromise antiretroviral activity, although some patients have failed zidovudine-containing regimens when only 41L or 215Y/F mutation was present. Tenofovir usually retains significant antiretroviral activity in the presence of multiple TAMs, if M184V is present. Unlike M184V and K65R, isolated TAMs cause only a small reduction in viral replicative capacity, but a combination of several TAMs can significantly reduce viral replication.

K65R

This relatively uncommon mutation is antagonistic to TAMs, and is the preferred mutational pathway for tenofovir. In addition, it can emerge following exposure to didanosine or abacavir. Stavudine has been rarely associated with K65R, which may explain some of the reported cases in resource-limited settings among patients without prior exposure to tenofovir, didanosine, or abacavir. Subtype C viruses appear to select K65R more rapidly than other HIV-1 subtypes and HIV-2. K65R is associated with cross-resistance to many NRTIs including abacavir, tenofovir, lamivudine, and didanosine, which provides a rational explanation for the observation that patients who have failed tenofovir-containing ART because of resistance may also fail abacavir or didanosine, and vice-versa.

The likelihood of developing K65R is influenced by the ART regimen: (1) risk is increased in treatment-naive patients who receive tenofovir plus abacavir, didanosine plus abacavir, or tenofovir plus didanosine; and (2) the presence of TAMs or zidovudine in a regimen diverts resistance pathways away from K65R. K65R appears to increase viral susceptibility to zidovudine. Viruses with K65R mutation, like M184V, have replicative capacity that is approximately 50% of wild-type, thus the combination of K65R and M184V results in a virus with very significant reduction in replicative capacity.

Other NRTI-Associated Mutations

NRTI cross-resistance has also been associated with Q151M and T69 insertions. L74V occurred frequently with didanosine monotherapy, but it is infrequently encountered now that didanosine is usually combined with other ARV drugs. Also, L74V is one of the mutational pathways selected by abacavir. The presence of L74V and M184V leads to abacavir and didanosine resistance plus some resistance to tenofovir. Patients who fail abacavir or didanosine due to L74V may harbor small populations of K65R, which translates to increased risk of tenofovir failure, if exposed to the drug.

NNRTI Mutations

The most common mutations seen in persons on NNRTI (nevirapine or efavirenz) therapy are K103N and Y181C, which cause high-level NNRTI cross-resistance. Other notable mutations include V106A, Y188C/L/H, and P225H. Because of the ease of developing resistance against NNRTIs, these drugs are said to have a low genetic barrier against resistance, like lamivudine and emtricitabine. Among poorly adherent patients who fail initial NNRTI-based ART (the combination most
commonly used in first-line ART in resource-limited settings), the most common mutations are NNRTI associated, followed by M184V.

NNRTIs have prolonged steady-state half-lives (25–32 hours and 40–55 hours for nevirapine and efavirenz, respectively), compared with other antiretroviral drugs. As a result, they remain in circulation at therapeutic concentrations for several days, and at subtherapeutic concentrations for up to several weeks after discontinuation. Thus, simultaneous discontinuation of all the drugs in an NNRTI-based regimen may lead to a period of unintentional NNRTI monotherapy since other drugs clear faster from the blood. This predisposes to NNRTI resistance, especially among patients with high viremia. Although the best strategy to discontinue NNRTI-based regimens is debated, most authorities recommend stopping the NNRTI followed by the NRTI(s). More controversial is the optimal length of time between stopping the NNRTI and stopping the “NRTI tail.” Recommendations have ranged from four to five days to as long as four weeks, while most agree that a one-to-two-week NRTI tail is reasonable.

PI Mutations
In general, single mutations in the protease gene cause relatively low-level resistance that does not significantly compromise clinical efficacy, but exceptions include D30N and I50L, which cause high-level resistance to nelfinavir and atazanavir, respectively. The likelihood of developing resistance can be reduced by adding low-dose ritonavir to “boost” the pharmacokinetics of the PI (except nelfinavir). This is because ritonavir inhibits gastrointestinal and hepatic cytochrome P450 (CYP450) enzyme systems, which are necessary to metabolize PIs. As a result, ritonavir improves the pharmacokinetic parameters of the co-administered PI, including the trough concentration (C_{min}) and overall drug exposure as measured by the area under the plasma concentration versus time curve (AUC). These changes allow the use of lower PI doses. Also, the inhibitory quotient (ratio of C_{min}/concentration needed to inhibit viral replication by 50% [IC_{50}]), which influences the likelihood of developing resistance mutations, is improved with boosted PIs. In summary, ritonavir-boosted PIs generally have improved potency and much reduced risk of resistance compared with unboosted PIs.

SINGLE-DOSE NEVIRAPINE, OTHER NONSUPPRESSIVE ART REGIMENS, RESISTANCE, AND TREATMENT FAILURE
One of the most common uses of nonsuppressive ART in resource-limited settings is sdNVP for PMTCT. Although recommended by WHO and unavoidable in certain situations (for example, women who present in labor), the main criticism of this intervention is that it predisposes to the development of K103N and Y181C mutations, which cause cross-resistance to nevirapine and efavirenz. The incidence of these mutations can be reduced by co-administering a short course of AZT/3TC to mother and baby. These mutations tend to fade over time, but may remain detectable for several years in some patients, and can be transmitted to the infants of affected women. Factors associated with delayed fading include high pre-sdNVP viral load and perhaps viral subtype.

The major clinical concerns related to the resistant mutations that can follow sdNVP are subsequent reduction in the effectiveness of ART that contains nevirapine or efavirenz, and reduced success of sdNVP in future pregnancies. Recent preliminary studies, however, have shed some light on the magnitude of these risks and provided justification for continued use of sdNVP when the woman is ineligible for combination ART for her own disease and better options do not exist. The first finding was the absence of a significant
difference in the efficacy of sdNVP between first versus second use.48,49 Equally notable were the studies that showed similar responses to NNRTI-containing combination ART among women with prior sdNVP exposure versus those without previous exposure, provided the combination ART was started at least six months after the sdNVP. Patients who initiated NNRTI-based ART within six months of sdNVP had poorer outcomes.30,31

Taken together, these findings suggest that despite the propensity of sdNVP to induce resistance mutations, it can be reused in subsequent pregnancies, and NNRTI-containing combination ART can be used in sdNVP recipients, but it is best to delay its use until at least six months after the exposure to sdNVP. Researchers are trying to reconcile the relative effectiveness of NNRTI-containing ART in patients who had evidence of NNRTI mutations after sdNVP only versus its lack of effectiveness in patients who failed previous NNRTI-containing ART. One yet to be proven hypothesis is that the quantity of resistant virions and archived mutations is much smaller after sdNVP alone; hence, it may be easier for it to be permanently overwhelmed by wild-type.

Another common, but certainly more harmful, scenario of nonsuppressive ART in resource-limited settings occurs through its provision by health providers with no experience in ART. This poses both short-term and long-term danger to individual patients and public health because it provides an ideal environment for iatrogenic resistance. To reduce this, adequate training should be provided to those who prescribe ART, and treatment outlets expanded by integrating them into existing healthcare infrastructure. Further, minimum monitoring capabilities should be made available, and strong systems put in place to fend off the threat of drug adulteration. Public enlightenment on the hazards of combining herbal preparations with ART should be undertaken. Unchecked inappropriate use of anti-HIV drugs can engender large-scale iatrogenic resistance and seriously limit the morbidity and mortality benefits that are derivable from ART.

**PRACTICAL APPROACH TO TREATMENT FAILURE**

Treatment failure occurs in approximately 30% of patients undergoing initial therapy,32 although it can be as low as 5% or may exceed 50% depending on the particular clinical setting and patient population.33-37 The most common cause of treatment failure is poor adherence as demonstrated by two observations: first, virologic failure rates can be as low as 5% when adherence is enforced such as through directly observed therapy (DOT) in correctional facilities;57 and second, patients failing initial therapy most commonly have drug-sensitive virus.58

**Optimizing Adherence to Prevent Resistance**

The management of treatment failure starts with its prevention, and the most effective tool from both cost and clinical perspectives is optimization of adherence in all patients. In general, timely and appropriate ingestion of at least 95% of prescribed ART is essential.59 The foundation for excellent adherence should be laid before the first dose of ART is prescribed, and systems for continual reevaluation and reinforcement should be in place. To improve adherence, selected ART should be simple, well tolerated, and have the fewest number of pills and a single daily dose if possible. Treatment literacy should be encouraged by educating patients about their regimen, including how to address adverse effects and contact their providers if needed; otherwise, they are likely to stop taking prescribed medications once they associate it with untoward effects. Further, support structures should be developed around each patient. The support models that have been used successfully in resource-limited settings...
differ in their specific methodologies, but most link patients to other people for motivation and assistance with disclosure and other psychosocial issues. In addition, the treatment supporters provide practical support with adherence and management of adverse effects. One model in Haiti used community-based health workers (accompagnateurs) to provide DOT, while other models used treatment partners (a relative or close friend) to promote adherence. In the clinic, all cadres of staff should be involved in adherence promotion, and specially trained counselors should be utilized whenever feasible. Tools such as pillboxes, drug identification charts, diaries, and educational materials are useful, especially if they are culturally competent. Finally, adherence should be addressed at every medical encounter, and a detailed record of drug pickup patterns should be kept. As ART programs expand, further research will be needed to identify best practices for treatment adherence support.

**Diagnosis of Treatment Failure**
The criteria used to define treatment failure are influenced by local resources and guidelines. In general, clinical, immunologic, and virologic factors are considered (Table 1).

### Table 1. Recognition of Treatment Failure: Adapted from the WHO 2006 Guidelines for Resource-Limited Settings

<table>

<tr>
<td>Virological</td>
<td>Persistent viral load &gt; 1,000 copies/ml</td>
</tr>
</tbody>
</table>

*Viral load is the earliest and best indicator of treatment failure.

**Managing First-Line Treatment Failure**

**Patients with Poor Adherence**

When confronted with a patient who is failing initial ART, the first step should be to determine the patient’s adherence. This can be done by appraising the pattern of ART pickup from the pharmacy, direct patient questioning, and a review of adherence tools such as drug diaries and pillboxes. In doing this, the clinician must recognize that the usefulness of these exercises in general, and direct patient questioning in particular, is directly linked to the skill with which the inquiry is undertaken and the quality of collected data. For example, the question “You have not been skipping your medications, right?” probably has a greater likelihood of eliciting an erroneous response than “How many doses have you missed in the last three days?” or “Tell me how you have been doing with the medications.” Further, the clinician should bear in mind that admissions of poor adherence are almost always accurate; claims of excellent adherence may be exaggerated; and health-care providers are often inaccurate in their subjective estimation of a patient’s level of adherence. Given the complexities of assessing adherence, clinicians should be prepared to apply both the art and the science of medical practice and expect surprises.

If a history of poor adherence is elicited, the clinician and patient should identify reversible
causes, and craft practical interventions to correct them. The underlying cause may be as simple as the inability to reach the ART site because of transportation problems or it may be something more complex such as deliberate avoidance of the clinic because of concerns about future discrimination and stigmatization, domestic abuse, or substance abuse. Also, requiring co-payment (no matter how little) from patients before they are given ART has been identified as a barrier to adherence. In appropriate settings, good results may be derived from referring patients to structured adherence programs where they can interact with other HIV-seropositive patients or adherence counselors.

Patients failing due to poor adherence should continue the initial regimen after corrective measures have been undertaken as it stands a good chance of being effective. Plans should be made to reevaluate in the near future. On the other hand, patients who fail despite proven adherence over several months likely harbor resistant virus and may need ART change.

2. Treatment Failure Despite Good Adherence
It is not uncommon for a patient to fail while all objective and subjective assessments indicate greater than 95% adherence to prescribed ART. In this situation, the clinician has to consider many possibilities, including the following:

Drug-drug interactions. This is particularly applicable to some resource-limited settings since patients often combine herbal medications with prescribed ART. It is also common for patients to self-prescribe “immune-boosters.” Some of these compounds have yet uncharacterized interactions with ARTs and should be avoided. Also, the integrity of the ART that the patient is taking should be confirmed. Drug adulteration—the addition of an impure, cheap, or unnecessary ingredient to cheapen or falsify a preparation—though not reported yet, is a potential hazard that merits continual vigilance. Patients who fail due to drug-drug interactions can have a retrial of initial ART after discontinuing the unnecessary adjuvant.

Current inappropriate ART. It is insufficient to document that a patient is on “ART.” The clinician must ascertain the specific components being used because the patient may be receiving an inappropriate combination.

Presence of resistant virus before initiating treatment. For patients failing initial NNRTI-based ART, a history of sdNVP during previous pregnancy should be excluded since this may explain treatment failure, which is more likely if combination ART was initiated within six months of the sdNVP exposure. Also, patients who have received inappropriate ART combinations in the past may harbor resistant strains. Primary resistance, or infection with HIV-2 or HIV-1 group O, which are constitutively resistant to NNRTIs, should be considered as well.

Inadequate dosing. Resistance may develop during treatment due to inadequate dosing. One scenario for this is failure to adjust the drug dose following weight gain, particularly in pediatric patients as well as adults with low baseline weight.

Resistance Testing
Resistance testing provides useful information, although its availability in resource-limited settings is currently limited to just a few tertiary institutions and internationally supported programs. There are two types of resistance tests: genotypic and phenotypic resistance assays. These tests are better at forecasting the drug(s) that a patient is not likely to respond to. Resistance mutations that account for less than 20% of the total viral pool in the tested sample are easily missed. Resistance tests are more accurate if performed while the patient is on ART or as close to the time of discontinuation as possible. Tests performed off ART are prone to errors since wild-type virus is likely to be dominant, while
resistant mutants, if present, may exist in subpopulations that are below the limits of detection.

Genotypic testing utilizes techniques such as nucleic acid sequencing or hybridization to detect point mutations in the viral genome. It can be completed in one to two weeks, whereas phenotypic testing requires a much longer time. Also, genotyping is less technically cumbersome, cheaper, and somewhat better at detecting resistant mutants that are present in low concentrations. Standard phenotypic resistance testing involves direct measurement of viral susceptibility to various drugs, expressed as the drug concentration required to inhibit viral growth by 50% (IC\textsubscript{50}). Resistance to a drug is presented as the fold-change (ratio of the IC\textsubscript{50} of sample virus to the IC\textsubscript{50} of wild-type virus), which has to be evaluated for clinical relevance. In general, interpretation of genotype requires more expertise compared with phenotype, especially in heavily treatment-experienced patients, who may harbor multiple, complex, and poorly characterized mutations. Clinical outcome information is not yet available for some mutations, especially those associated with non-B HIV subtype.

While resistance testing in all failing patients is clearly not feasible, a public health approach that includes centrally coordinated monitoring and evaluation can reduce resistance and inform clinical management in resource-limited settings. The specific activities should include pharmacovigilance to ensure early detection and accurate characterization of the incidence and clinical features of adverse effects caused by antiretroviral drugs, since adverse effects are a leading cause of poor adherence, and indirectly resistance. The findings from monitoring and evaluation activities, including pharmacovigilance, should be incorporated into ART guidelines. For example, the recent change in the recommended dose of stavudine, a commonly used NRTI in resource-limited settings, from 40 milligrams twice daily to 30 milligrams twice daily is aimed at reducing peripheral neuropathy and suboptimal adherence associated with the higher dose. Monitoring and evaluation should be used also to determine locally sustainable best practices for uninterrupted procurement of antiretroviral drugs, drug storage, clinician training, and patient follow-up. Trends in transmitted and secondary resistance should be followed and applied to the care of HIV-infected patients and the prevention of new infections.

**Selecting a Second-Line Regimen**

Once it is determined that a patient is failing initial ART despite addressing adherence and related issues, a prompt treatment change is imperative. One of the major barriers to achieving this goal in resource-limited settings is the dearth of facilities for HIV RNA quantitation (viral load). Of the three potential parameters for determining failure (Table 1), an increase in viral load is the sentinel event, and typically precedes a decline in CD4 count by approximately six months, which itself precedes clinical manifestation(s) by several months or even years. Thus, a reliance on parameters other than viral load for identifying clinical failure implies there is likely to be a delay of six months or longer before treatment failure is recognized. This delay has potentially serious implications since patients who are inadvertently left on a failing regimen run the risk of developing (acquiring) more mutations, which can compromise future ART. In one study, 77% of patients left on a virologically failing regimen (viral load > 400 copies/mL) acquired one or more mutations over an average follow-up period of six months. Given the importance of viral load determinations in assessing treatment success and failure, accelerated research initiatives to develop locally adaptable and sustainable techniques are a priority for resource-limited settings.

Second-line combination ART should contain at least two new drugs (Table 2). Although WHO
FROM THE GROUND UP: ESTABLISHING A FRAMEWORK FOR SUCCESS

...can be a boosted PI plus two new NRTIs or other options shown in Table 2.

...two NRTIs in the new regimen should be selected based on the initial combination. Tenofovir is a particularly valuable component of second-line regimens because it often retains activity when other NRTIs are no longer effective; however, it is often unavailable. Disturbingly, high rates of resistance to tenofovir in patients without prior exposure to the drug have been reported recently in Malawi and other parts of sub-Saharan Africa, so this drug is not always the best option, and its use is best guided by knowledge of local mutational patterns. The combination of tenofovir and zidovudine has reduced propensity for development of the K65R mutation and overall bidirectional synergy, making it a desirable combination in many situations. Didanosine plus tenofovir has been associated with low CD4 counts, although it is virologically effective. The dose of didanosine should be adjusted downward if they are co-administered. Regardless of the two new NRTIs selected, it is reasonable to consider leaving lamivudine or emtricitabine as an additional agent. This is to preserve M184V mutation, which reduces viral replicative capacity, induces hypersusceptibility to some other NRTIs, and increases viral fidelity.70 It is also important to remember that discontinuation of hepatitis B virus active drug (lamivudine, emtricitabine, or tenofovir) in a patient with active hepatitis B can result in a life-threatening hepatitis flare.

Treatment after Second Failure

The management of patients who have failed second-line ART is complicated by the absence of genotype and phenotype resistance testing in most resource-limited settings. Virtually all salvage combinations are more complex than those used in earlier regimens, and adherence may be more difficult...
because of this. In general, it is reasonable to include lamivudine or emtricitabine in the regimen for the same reasons it is valuable in second-line regimens.\(^7\) Boosted PIs, tenofovir, and other NRTIs may also be beneficial, and local experts should be consulted whenever possible. Although newer drugs such as novel PIs and enfuvirtide, a fusion inhibitor, are frequently used in industrialized countries, these are not available in most resource-limited settings at this time. An example is tipranavir, a ritonavir-boosted PI that may be effective in some multi-drug-resistant, heavily pretreated cases when combined with an optimized background of other agents.\(^7\) Also, darunavir, another novel PI, has shown at least comparable efficacy and probably better tolerability and safety in similar patients.\(^7\) Etravirine is a second-generation NNRTI with activity against nevirapine- and efavirenz-resistant viruses,\(^7\) while maraviroc\(^7\) and raltegravir\(^7\) are a valuable CCR5 receptor antagonist and integrase inhibitor, respectively. Novel compounds like these have significantly expanded options for salvaging advanced patients, and it is inevitable that they will be needed in resource-limited settings (Table 3).

Even when the ART options available to a highly resistant salvage patient fail to fully suppress plasma virus, continuation of such a regimen may stabilize the patient’s CD4 cell count and clinical status\(^7\) until better options become available. Another strategy that has preliminarily demonstrated some benefit, compared with no therapy at all, is the use of lamivudine (and likely emtricitabine) monotherapy in patients who already harbor M184V. Expected benefits include slower rates of CD4 cell decline, viral rebound, and recovery of HIV-1 replication capacity.\(^8\)

<td>Previous exposure to NRTIs, NNRTIs, and PIs with evidence of resistance to drugs in all the classes</td>
<td>Significant benefit can be derived from using a regimen that includes at least two new agents that have full activity along with an optimized combination of NRTIs. Drugs that are likely to have full activity in this context include darunavir/r, raltegravir, enfuvirtide, and maraviroc. Etravirine potentially has a role as well but it should be combined with a potent boosted-PI such as darunavir/r and other active drugs in patients with prior exposure to nevirapine or efavirenz.</td>
</tr>
</tbody>
</table>

Notes:

- The utility of the CCR5 co-receptor antagonist, maraviroc, is limited to persons with exclusively CCR5-tropic virus. The assay for CD4 co-receptor tropism is not available in resource-limited settings at this time.
- Tipranavir cannot be co-administered with etravirine. It requires a higher dose of ritonavir, and has been associated with fatal and nonfatal hepatitis and intracranial hemorrhage.
- Darunavir/r has a similar side-effect profile to other boosted PIs and has been associated with rashes, including Stevens-Johnson syndrome.

Drug-Drug Interactions in HIV Disease Management

Hermann Bussmann\textsuperscript{a} and Kimberly K. Scarsi\textsuperscript{b}

\textsuperscript{a}Harvard School of Public Health, United States
\textsuperscript{b}Division of Infectious Diseases, Northwestern University Feinberg School of Medicine, United States

PHARMACOTHERAPY IS AN ESSENTIAL component of HIV disease management. Treatment with multiple agents is often necessary to cure or control HIV/AIDS-related illnesses, to treat or prevent non-HIV-related acute or chronic conditions (e.g., arterial hypertension, hyperlipidemia, seizure disorders), and eventually to suppress HIV viremia. As interactions between different drugs might jeopardize the desired treatment outcome, health-care workers who prescribe, dispense, and/or monitor treatment effects need to be aware of potential drug interactions, as do the patients themselves.

Drug interactions can be defined as a change in the pharmacology of one drug in the presence of another drug. The combined effect of two or more drugs can be synergistic when the overall effect is greater than the sum effects of the individual drugs; it is antagonistic when one drug reduces or nullifies the effect of another drug. In some instances, expected drug-drug interactions can be beneficial, such as the pharmacologic enhancing effect of boosted protease inhibitors (PIs), which will be discussed later.

Regularly updated Web-based interactive drug interaction charts are available to help health-care providers cope with ever-increasing information on drug-drug interactions in clinical practice.\textsuperscript{1,2} Fortunately, only a minority of reported drug-drug interactions require absolute dose modification or drug substitution, but monitoring of toxicity or efficacy in light of these interactions is critical. Challenges specific to resource-limited settings include limited accessibility to existing, easy-to-use Web-based references; a limited range of available alternative drugs; and a lack of lab-based monitoring tools necessary to measure drug levels, toxicities, and treatment efficacy.

This chapter aims to summarize the most clinically significant drug interactions encountered in HIV disease management, to explain the underlying pharmacologic principles, and to recommend appropriate clinical management strategies.

KEY MECHANISMS OF DRUG INTERACTIONS

Successful pharmacotherapy depends on the administration of a drug dose sufficient to achieve the desired clinical effect with minimal toxicity. The relationship between drug dose and effect can be divided into pharmacokinetic (the body’s impact on the drug and the resulting drug concentration)
and pharmacodynamic (the drug’s effect on the body at a given concentration) components. The drug concentration at the site of action provides the link between the pharmacokinetic and pharmacodynamic properties of a drug and is an important parameter in the approach to establish rational drug dosing. The area under the plasma concentration time curve (referred to as “area under the curve,” or AUC) is a commonly used pharmacokinetic parameter to describe the bioavailability and clearance of a particular drug and to measure the effect of drug-drug interactions.

Here we describe mechanisms of drug interactions as they relate to commonly used drugs to treat HIV-related illnesses.3

Pharmacokinetic Drug Interactions
Pharmacokinetic drug interactions can occur at any step from the initial administration of the drug to its final clearance from the body, in particular during the process of drug absorption, biotransformation (activation or inactivation), and elimination.

A major site of drug metabolism is the liver. Biotransformation of drugs is broadly divided into two categories, namely drug oxidation (e.g., by the cytochrome P450 [CYP] enzyme system, which is a phase I reaction) and drug conjugation (e.g., glucuronidation or acetylation, which are phase II reactions).

CYP Metabolism
Many drug interactions occur among drugs that are metabolized by the CYP enzyme system, either when two co-administered drugs are metabolized by the same CYP enzyme or when one drug inhibits or induces (slows down or speeds up, respectively) the activity of a CYP enzyme impacting the biotransformation of the other drug.

The list of drugs that are substrates for CYP enzyme metabolism is long and includes the non-nucleoside reverse transcriptase inhibitors (NNRTIs), the PIs, and drugs used to treat opportunistic infections, such asazole antifungal agents, anti-TB drugs, macrolide antibiotics, lipid-lowering medications (the statins), certain antidepressants (serotonin uptake inhibitors such as fluoxetine), anticonvulsants (carbamazepine, phenobarbital, and phenytoin), anxiolytic drugs (benzodiazepines), oral contraceptives, drugs used to treat erectile dysfunction, and certain recreational drugs such as methylenedioxymethamphetamine (ecstasy) or methadone. In addition to being metabolized by the CYP enzyme system, many of these drugs also induce or inhibit the CYP enzyme activity.

CYP enzyme inhibitors: Most PIs are CYP inhibitors, leading to increased concentrations of simultaneously administered drugs that are metabolized via CYP enzymes. Ritonavir is the most potent inhibitor and, even in low dosages (50–100 mg per day), is able to increase the serum levels of other co-administered PIs (see also under PI boosting). Among PIs, saquinavir has the mildest inhibitory effects. Other important inhibitors are theazole antifungal drugs (itraconazole, fluconazole, and ketoconazole), the macrolide antibiotics (erythromycin and clarithromycin), and the H2 blockers (cimetidine and ranitidine).

CYP enzyme inducers: Inducers enhance the action of CYP enzymes, leading to decreased concentrations of concomitantly administered drugs metabolized by CYP enzymes. The strongest inducer is the anti-TB medication rifampicin. Other important inducers include nevirapine (NVP) as well as certain anticonvulsant drugs, namely phenytoin, carbamazepine, and phenobarbital. Some protease inhibitors have the potential to also induce CYP enzymes, so careful review of drug interaction potential based on the specific ARV combination being used is warranted.

CYP enzyme mixed inhibitors and inducers: Inducing or inhibiting effects are not limited to
individual drugs. For example, some drugs, such as efavirenz (EFV), exert both inhibitory and inducing effects. In clinical situations, EFV has been demonstrated to act primarily as an inducer (such as when combined with PIs); however, laboratory studies have shown that EFV is also an inhibitor of CYP, making it difficult to anticipate the exact interaction without drug-interaction study data. Similarly, ritonavir, a strong inhibitor of the CYP3A enzymes, can also induce the metabolism of oral estrogens, theophylline, atovaquone, and warfarin via other CYP enzymes.

Renal Elimination
All nucleoside reverse transcriptase inhibitors (NRTIs) undergo primarily renal excretion, with the exception of zidovudine (ZDV), which is metabolized by hepatic glucuronidation and subsequently excreted via bile and urine, and abacavir, which is metabolized via alcohol dehydrogenase. Drugs that are inhibitors of renal tubular secretion, such as trimethoprim, probenecide, and cimetidine, may inhibit NRTI elimination. However, the clinical importance of these interactions is unknown.

Transporter Proteins
Transporter proteins are cell membrane carriers that are specialized to expel foreign molecules and may be a key determinant of the underlying pharmacokinetic considerations for an individual drug. One of the best-characterized drug transporter proteins is P-glycoprotein. P-glycoprotein is implicated in various drug-drug interactions involving treatment with PIs, rifampicin, immunosuppressants, antibiotics, antifungal medications, and digoxin. Tipranavir is a potent P-glycoprotein inducer and should be used with caution or not at all in conjunction with other PIs that are substrates of P-glycoprotein.

Pharmacodynamic Drug Interactions
Pharmacodynamic drug interactions can occur when drugs with a similar biological effect also overlap in their toxicity profile or when two concurrently administered drugs compete for activity at a site of action, such as ZDV and stavudine (d4T). Overlapping toxicities are discussed later in this chapter.

Other Factors Influencing Drug Response
The drug response may be influenced by various physiological factors, which include age, gender, and underlying hepatic and renal function, and also by interaction with concomitant medications. In recent years, drug responses have shown to also be under the influence of host genetic factors, a fact that has sparked off the rapidly evolving field of pharmacogenetics. Variation in genes involved in pharmacokinetic or pharmacodynamic pathways may result in altered metabolism or increased susceptibility to adverse drug effects. For example, the major histocompatibility complex HLA B*5701 allele has been associated with abacavir hypersensitivity. A single nucleotide polymorphism (SNP) in the CYP2B6 enzyme has been linked to heightened plasma exposure to EFV and may increase the risk for central nervous system toxicity. A variant in the gene that codes for the drug transporter protein P-glycoprotein has been suggested to influence plasma drug concentrations achieved by P-glycoprotein substrates and may also impact the CD4 cell response.

Predicting Drug Interactions
Drug interactions can influence the efficacy and/or the tolerability of a drug regimen. Anticipating the resultant interaction between drugs can often be complex, but information pertaining to drug-drug interactions is constantly expanding. This chapter discusses basic principles and underlying mechanisms of drug interactions to assist all health-care
workers involved in HIV care in identifying potential drug interactions.

As discussed above, interactions impacting drug efficacy can be due to the inducing or inhibiting effect of drugs on the activity of the CYP enzyme system, or by impaired drug absorption, caused either by drug-food interaction or by drugs that change the gastric environment.

Drug tolerability can be affected when a concomitant medication or condition increases the drug concentration to toxic levels (dose-related toxicity) or when concomitant drugs exert similar adverse effects (overlapping toxicity).

Drug interactions with major clinical implications will be discussed in the following sections.

**PI Boosting**

Interactions between ritonavir and other PIs are used advantageously in a process called PI boosting. Ritonavir is the most potent inhibitor of the CYP3A4 enzyme among the available PIs. A small, virologically ineffective dose of ritonavir will significantly increase the blood concentration of the co-administered active PI. Ritonavir also inhibits the activity of P-glycoprotein, impacting the absorption and distribution of other drugs that are substrates of P-glycoprotein, including the other PIs. Ritonavir dramatically increases the absorption and overall pharmacokinetic exposure of most other PIs.

PI boosting thus reduces pill burden, allows for a more favorable dosing interval, and may remove food co-administration restrictions. Commonly boosted PIs include lopinavir, saquinavir, indinavir, and atazanavir. In order to achieve virologically effective concentrations, newer PIs such as lopinavir, darunavir, and tipranavir cannot be administered without the co-administration of ritonavir. A commonly used formulation that combines ritonavir and lopinavir into a single pill is Kaletra or Aluvia (lopinavir/ritonavir, LPV/r). The only PI that does not benefit from ritonavir boosting is nelfinavir, which is metabolized via several isoenzymes in addition to CYP3A4.

**Drug-Food Interactions**

Generally, it is convenient to take oral medications along with food or at mealtimes. A few drugs used for treatment of HIV-related illnesses, however, require a specific gastrointestinal tract environment for optimal absorption. The original formulation of didanosine (ddl, Videx) contains a buffering agent to protect ddl from degradation by gastric acid and needs to be taken on an empty stomach (30 minutes to one hour before or two hours after a meal) for optimal absorption. The newer, enteric-coated ddl (Videx EC) does not contain the buffer, but this formulation still requires administration on an empty stomach. PIs (except unboosted indinavir) should generally be given with food, to enhance absorption and decrease side effects. EFV should be given on an empty stomach, or with a low-fat snack, as taking it with food, especially a high-fat meal, leads to higher EFV concentrations in the blood and may increase side effects. Tenofovir is recommended to be given with food in European guidelines, while U.S. guidelines suggest it may be given with or without food. Unboosted indinavir should be taken on an empty stomach, or with a low-calorie snack, to ensure adequate absorption. Other antiretrovirals (ARVs) not mentioned here can generally be given without regard to food.

Other drugs commonly used in HIV comorbidity management also have some gastric environment restrictions. Depending on the type of erythromycin base given and the type of tetracycline, administration on an empty stomach may be preferable. It is recommended that griseofulvin and itraconazole capsules be taken with food. Fluoroquinolones and tetracyclines are prone to bind with other compounds (i.e., aluminum, iron,
calcium, and magnesium) so co-administration with products containing these elements will affect their bioavailability. Doses of the antibiotic and cation element should be separated by two hours when a patient requires both products.

Some drugs require a specific gastric acidity to be properly dissolved and absorbed, such as ddI, discussed above. When patients receive concomitant medications that change the gastric acidity, such as antacids, H2 receptor blockers, or proton pump inhibitors, caution should be used with some HIV therapies. See Table 1 for some common HIV therapies that require caution when administered with gastric-acid-reducing agents. Consult a drug interaction reference for specific recommendations based on the acid-reducing agent and co-administered drug, as this interaction may or may not be overcome by separation of the doses.

### Interactions between NNRTIs/PIs and Other Drugs

The whole spectrum of confirmed and theoretical drug interactions is beyond the scope of this overview. However, a few classes of medications deserve special mention, as they are routinely prescribed in HIV clinical practice and their drug-drug interactions may be clinically significant. This information is generalized and not intended as specific medical advice. See Table 2 for an overview.

and triazolam; (d) all ergot alkaloid derivatives used for the treatment of migraine headaches; and (e) other medications, including cisapride, pimozide, and bepridil.

**Simvastatin and Lovastatin**
The two lipid-lowering medications simvastatin and lovastatin are contraindicated with PIs. The inhibitory effect of PIs on the CYP system raises the levels of these statin drugs to toxic levels, leading to life-threatening side effects such as rhabdomyolysis and renal failure. The lipid-lowering drugs pravastatin and fluvastatin are safe alternatives.

**Astemizole and Terfenadine**
Similarly, co-administration of PIs, EFV, and/or other CYP inhibitors with the antihistamines astemizole and terfenadine is contraindicated, as case reports of serious adverse events, including death and cardiac arrhythmias, have been recorded when levels of these drugs exceed the upper therapeutic threshold. As a result, these antihistamine medications have been removed from the American market. Chlorpheniramine (Allergex) is a safe antihistamine alternative for the treatment of mild to moderate allergic symptoms, including pruritus, rash, and other signs and symptoms related to allergic reactions.

**Midazolam and Triazolam**
The benzodiazepines midazolam and triazolam are contraindicated for patients on PIs and EFV. Their concentrations can reach dangerously high levels in the presence of CYP inhibitors, potentially causing fatal respiratory arrest. Safer alternatives include lorazepam, oxazepam, and temazepam.

**Ergot Alkaloid Derivates**
Ergot alkaloid derivates should be avoided in conjunction with PIs, EFV, and other CYP inhibitors. This may lead to potentially life-threatening ergot alkaloid toxicity, characterized by peripheral vasospasm, ischemia, thrombosis, tachycardia, and hypertension. Safe alternative treatment of migraine includes nonsteroidal anti-inflammatory drugs (NSAIDs), triptans, metoclopramide, and prochlorperazine.

**Cisapride**
Toxic levels of cisapride can be reached when this drug is co-administered with CYP inhibitors (azole antifungals, macrolides, PIs, EFV, and cimetidine). These interactions may lead to prolongation of the QT interval, cardiac arrest, or sudden death. Cisapride has been withdrawn from the American market. Safe alternatives with most ARVs are antacids (Maalox, milk of magnesia, and metoclopramide).

**Pimozide**
Recent reports also caution against the use of the antipsychotic drug pimozide in combination with PIs or EFV. Inhibition of the metabolism of pimozide by PIs or EFV may lead to the development of life-threatening cardiac arrhythmias.

**Bepridil**
The calcium channel blocker bepridil is contraindicated for concomitant use with PIs or EFV. Bepridil has been removed from the American market.

**Drugs Requiring Dose Modification or Cautious Use**
The following drug classes may contain drugs that interact with ARV drugs: azole antifungals, statins, anticonvulsants, anti-TB medications, antimalarials, macrolide antibiotics, hormones (oral contraceptives), erectile dysfunction medications, anticoagulants, calcium channel blockers, antipsychotics, and antidepressants.

**Azole Antifungals**
Due to the potential for considerable bidirectional interaction between the azole antifungals and the
ARV classes of PIs and NNRTIs, caution may be required when such agents are concomitantly administered. In general, fluconazole can safely be used with NNRTIs and PIs. However, the concentration of NVP is increased when given with 200 mg of fluconazole. Therefore, patients receiving this combination should be monitored closely for NVP-related side effects.

Ketoconazole anditraconazole levels are increased when co-administered with ritonavir-boosted PIs, so in some cases the drug dosages of itraconazole and ketoconazole should not exceed 200 mg daily. Nelfinavir co-administration with ketoconazole or itraconazole appears to have less potential for this interaction. Ketoconazole and itraconazole levels are reduced by EFV and NVP, and alternate antifungal agents such as fluconazole should be strongly considered. Dose adjustment of the newazole antifungal agent voriconazole is required with ritonavir-boosted PIs and EFV because voriconazole’s clearance is decreased by these agents. Caution is also advised when co-administering voriconazole with NVP, as voriconazole levels may be decreased and NVP levels may be increased.

Statins
The clearance of the lipid-lowering drug atorvastatin is decreased by PIs. Therefore, when co-administering atorvastatin with a PI, the health-care worker should start with the lowest available atorvastatin dose (typically 10 mg) and monitor for toxicity before increasing the dose. The lipid-lowering drugs pravastatin and fluvastatin are safe alternatives.

Anticonvulsants
Bidirectional interactions can be expected when the anticonvulsants phenobarbital, phenytoin, and carbamazepine are co-administered with NNRTI- and PI-containing regimens. In general, anticonvulsant levels and overall virologic response (plasma viral load levels) should be monitored regularly.

Valproate (valproic acid), gabapentin (Neurontin), and lamotrigine (Lamictal) may be alternatives with lower potential for interactions. Valproate levels, however, may be decreased by concomitant ritonavir administration due to induction of CYP2C9 and glucuronidation.

Anti-TB Drugs
The anti-TB drug rifampicin (rifampin) induces the activity of a number of drug-metabolizing enzymes and has the greatest effect on the expression of CYP3A4 compared to other rifamycins (followed by rifapentine, while rifabutin is the least potent CYP inducer). In addition, rifampicin induces the activity of certain drug transporter proteins, such as intestinal and hepatic P-glycoprotein. As a result, the cellular and plasma concentrations of PIs are significantly reduced by rifampicin. Rifampicin also compromises the treatment effect of oral contraceptives, azole antifungals, corticosteroids, oral midazolam, triazolam, simvastatin, verapamil, and most dihydropyridine calcium channel antagonists. The use of rifampicin with PIs and NNRTIs needs special attention and will be discussed below.

Antimalarial Agents
Pharmacokinetic data regarding the combination of ARVs and antimalarials are just becoming available. Generally, halofantrine, lumefantrine, quinine, and amodiaquine may be impacted by NNRTIs and PIs. Because this is a common comorbidity in resource-limited settings, special attention will be given to this topic below.

Macrolide Antibiotics
Macrolide antibiotics are substrates and inhibitors of the CYP enzyme system. Clarithromycin has the potential to increase the level of NVP, and close monitoring for hepatic abnormalities is recommended. In the presence of EFV, clarithromycin levels may be reduced, and alternatives for clarithromycin should
be considered. A moderate increase in the concentration of clarithromycin is expected in the presence of LPV/r. Dose modification is not necessary if kidney function is normal. However, clarithromycin dose reduction should be considered in patients with renal impairment. The macrolide erythromycin should be avoided in the presence of ritonavir-containing PIs, as fatal cardiac arrhythmia has been associated with increased erythromycin levels in other clinical situations. Azithromycin is a safe alternative in the presence of PIs and NNRTIs. Most other antibiotics can be safely co-administered with ARVs.

**Hormones (Oral Contraceptives)**
The oral contraceptive ethinyl estradiol may interact with PIs and NNRTIs in complex ways. The clinical significance of these interactions has not been evaluated thoroughly, but co-administration may cause contraceptive failure (NVP, ritonavir, LPV/r, nelfinavir) or oral contraceptive side effects (EFV, atazanavir).

**Erectile Dysfunction Medication**
The levels of the phosphodiesterase inhibitors sildenafil, tadalafil, and vardenafil commonly used to treat erectile dysfunction are significantly increased in the presence of PIs and may be reduced in the presence of NNRTIs. Dose reduction is needed when co-administered with PIs.

**Anticoagulants**
The concentration of the anticoagulant drug warfarin, a drug with a narrow therapeutic index, may be altered when co-administered with PIs, especially ritonavir, or NNRTIs. Close monitoring of the anticoagulant effect is required when these drugs are co-administered.

**Calcium Channel Blockers**
The levels of calcium channel blockers nifedipine, verapamil, and diltiazem and the antiarrhythmic drug quinidine may increase in the presence of PIs or be reduced in the presence of NVP or EFV. These combinations should be used with caution, and calcium channel blocker dose adjustment should be guided by clinical response.

**Antipsychotics**
Many antipsychotic agents are metabolized via the CYP enzyme system, and drug interactions with ARVs are often very complex. Most antipsychotic agents can be affected by co-administration with PIs or NNRTIs; therefore, close monitoring of clinical response and toxicity is recommended.

**Antidepressants**
Tricyclic and selective serotonin reuptake inhibitor antidepressants can generally be combined with PIs and EFV. However, some changes in antidepressant concentrations have been shown. Therefore, close monitoring for efficacy and toxicity is recommended. St John’s wort, an herbal remedy, should be avoided as it has been demonstrated to decrease blood levels of PIs and NNRTIs.

**COMBINING PIs AND NNRTIs**

**PI/NNRTI Interactions**
Co-administration of PIs and an NNRTI is reserved for the management of specific cases, such as in salvage therapy involving multiclass drug resistance or as an NRTI-sparing regimen (e.g., to avoid the risk of lactic acidosis). Some data exist regarding drug interactions between these two classes to guide therapy.

The dual PI combination saquinavir/ritonavir 400/400 mg twice daily in combination with an NNRTI does not require dose modification. Clinicians should consider increasing LPV/r to 533/133 mg (or 600/150 mg of the new tablet version of Aluvia) twice daily in the presence of NNRTIs. Atazanavir must be boosted with
ritonavir in the presence of NNRTIs. Potential interactions between nelfinavir and NNRTIs exist, but alteration of drug doses may not be required. It is generally advisable to monitor liver enzymes when NNRTIs are used in combination with PIs, as both classes may cause hepatotoxicity.

**Dual PI Interactions**

Dual boosted PIs, also only used in specific cases, consist of two PI agents in addition to low-dose ritonavir.

The long-term safety and efficacy of LPV/r in combinations with other PIs has not been formally established. However, pharmacokinetic and clinical data on LPV/r combined with saquinavir (1,000 mg BD [twice a day]) suggest that this combination is a potential option for patients with prior treatment failure or toxicities. The combination of atazanavir (300 mg OD [daily]) and LPV/r resulted in appropriate drug concentrations of each agent in healthy volunteers. Dose adjustment and drug monitoring are recommended when LPV/r is co-administered with either nelfinavir or amprenavir.

The newer PIs tipranavir and darunavir are not recommended in combination with other PIs, as they have not been studied in dual PI combination or have shown existing interactions.

**INTERACTIONS INVOLVING NRTIs**

There are few known pharmacokinetic interactions that occur when NRTIs are co-administered with other drugs, in part because NRTIs are not metabolized by the CYP enzyme system. Emtricitabine, lamivudine, ddI, d4T, and tenofovir are primarily cleared by renal excretion, while ZDV is metabolized by hepatic glucuronidation and abacavir is catalyzed by alcohol dehydrogenase. A large alcohol dose might compete with abacavir clearance through competition with the alcohol dehydrogenase; however, this is currently a theoretical interaction.

Importantly, co-administration of the two thymidine analogues, ZDV and d4T, is contraindicated due to intracellular pharmacologic antagonism, which will compromise the antiviral effect of these drugs.

A few drug interactions have been reported that might affect the safety or efficacy of ZDV. Valproic acid and fluconazole, when co-administered with ZDV, have been shown to increase ZDV levels. Patients should be monitored closely for potential toxicity of ZDV. Limited data suggest that rifampicin decreases the concentration of ZDV, which may result in a partial or total loss of efficacy of ZDV. Advice on concurrent usage is conflicting and ranges from “should be avoided” (European summary of product characteristics) to “dose modification not warranted” (U.S. prescribing information). Similarly, tipranavir/ritonavir reduces plasma ZDV levels; the clinical relevance of these reductions has not been established but may decrease the efficacy of these ARV agents.

Tenofovir and ddI co-administration should be avoided because (a) this combination carries a high risk for developing drug resistance and (b) tenofovir increases plasma levels of ddI (both buffered and enteric-coated formula). If co-administration is needed, ddI should be dose reduced, and efficacy and ddI-associated toxicity should be closely monitored. Drug interactions have been reported between tenofovir and PIs; however, they are not known to be clinically relevant. One exception to this is the drug interaction between tenofovir and atazanavir. Due to still-unclear mechanisms, tenofovir reduces atazanavir concentrations; therefore, unboosted atazanavir should not be administered with tenofovir. Boosting atazanavir with ritonavir results in more consistent atazanavir concentrations that are similar to atazanavir concentrations without the presence of tenofovir. Conversely, tenofovir levels are increased when used with LPV/r or darunavir/ritonavir,
and the potential renal adverse effects should be monitored.12

NEW DRUG CLASSES
The development of new ARV drugs is rapidly advancing. Some of these drugs have different sites of action, such as fusion inhibitors, CCR5 antagonists, or integrase inhibitors. Information on the interactions of these drugs with other medications is still evolving. The fusion inhibitor enfuvirtide, in use for several years in developed countries, is a peptide drug (administered subcutaneously) and has a low potential for drug interactions. The integrase inhibitor raltegravir (Isentress, MK-0518) has recently been approved in the United States for the treatment of HIV-1 infection in treatment-experienced adults. Raltegravir is metabolized by hepatic glucuronidation and does not seem to influence drugs metabolized by CYP enzymes; however, drugs that affect glucuronidation (such as atazanavir or rifampicin) will result in a pharmacokinetic interaction. A second integrase inhibitor (elvitegravir) is in advanced clinical trials. The CCR5 antagonist maraviroc (Selzentry) was also recently approved for use in antiretroviral-experienced patients. Maraviroc is primarily metabolized by CYP3A enzymes and has complex dosing depending on the co-administered PIs or NNRTIs. Current information on the potential interactions of these drugs should be obtained from Web-based drug interaction charts or the manufacturers’ summaries of product characteristics.

OVERLAPPING TOXICITIES
A number of drugs used in the management of HIV disease have similar adverse-effect profiles. Table 3 categorizes frequently used drugs by their effect on specific tissues, such as the bone marrow, pancreas, kidney, liver, peripheral nerves, and skin. Hematological parameters should be monitored when combining ZDV with myelosuppressive drugs (e.g., anticancer treatment; antifungal treatment with amphotericin or flucytosine; or treatment or prophylaxis with cotrimoxazole, dapsone, or pyrimethamine). Didanosine and 4T combinations are contraindicated due to increased liver, pancreas, and neurotoxicity as well as the risk of lactic acidosis. The risk of liver toxicity is increased by several drugs, including anti-TB medication, alcohol, azole antifungals, NNRTIs, and PIs. Severe cutaneous adverse effects can be induced by NVP, abacavir, cotrimoxazole, and dapsone.

SPECIAL CONSIDERATIONS

Anti-TB Treatment plus Combination Antiretroviral Therapy
HIV/TB coinfection is a very common clinical condition in many developing countries. Treatment involves multidrug regimens with significant risk of drug interactions. Rifampicin, an indispensable component of standard first-line TB regimens, is also one of the strongest inducers of the CYP enzyme system and will interfere with dosing of NNRTIs, PIs, ZDV, and other drugs co-administered to manage TB disease. For example, the prednisolone dose should be increased when used together with rifampicin.33

Because rifampicin produces a significant lowering of NVP concentrations,34,35 the concomitant use of rifampicin and NVP is not recommended. A small pilot study showed that an increase of NVP (300 mg twice daily) can effectively increase NVP levels.36 However, this approach needs to be confirmed by a formal clinical trial to ensure safety and efficacy. The effect of rifampicin is less pronounced when combined with EFV37,38 (AUC 26% decrease). To compensate for this decrease, some experts recommend that the dose of EFV be increased to 800 mg per day in patients weighing more than 60 kg. However, some argue that this dose increase may not be necessary, irrespective of weight, and

Source: U.S. Department of Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents (Table 19, p. 84).16

Further research into the appropriate dose of EFV when combined with rifampicin is ongoing. Alternatively, physicians may consider switching to a triple NRTI combination for a variable period of time, depending on the TB treatment regimen. This is also a possible strategy for HIV-positive pregnant women on first-line combination antiretroviral therapy (ART) who develop TB.

While guidelines are conflicting regarding co-administration of rifampicin and ZDV, as rifampicin is reported to reduce the plasma ZDV concentration, this combination is widely used in resource-limited settings. The clinical impact of this reduction in plasma concentrations has not been established.

The co-administration of rifampicin and PIs will often require expert advice from TB and HIV specialists. Co-administration of rifampicin with PIs will reduce the PI plasma concentration by about 90%, greatly jeopardizing the success of the ART. The combination of saquinavir/ritonavir plus rifampicin had previously been recommended.
as an effective HIV/TB coinfection therapy.\textsuperscript{39} However, potentially life-threatening side effects, such as the risk of severe hepatocellular toxicity, have been reported from this co-administration.\textsuperscript{40,41} Therefore, rifampicin is contraindicated in patients taking ritonavir-boosted saquinavir as part of an ART regimen.

Co-administration of rifampicin and standard doses of LPV/r results in subtherapeutic concentrations of lopinavir and is not recommended.\textsuperscript{42} One study reported that either adding 300 mg ritonavir to the coformulated LPV/r for a total dose of LPV/r 400/400 mg BD, or increasing LPV/r to 800/200 mg BD, resulted in a favorable AUC for all drugs\textsuperscript{43}; however, more evidence regarding the safety and efficacy of this combination is needed before this can be routinely recommended.

Where available, rifabutin, also a rifamycin derivate, can be used with most PIs, provided that the rifabutin dose is reduced, as rifabutin is metabolized by the CYP enzymes inhibited by most PIs. Conversely, EFV acts as a CYP inducer to reduce rifabutin concentrations, necessitating an increase in the dose of rifabutin.

It is particularly important to remember that after rifampicin is discontinued, the concentrations of many other drugs used by the patient will increase as the induction starts to wear off. Patients should be encouraged to notify their health-care providers if they stop or change any medications so the proper dosage adjustments can be made.

**PI Dosing in Pregnancy**

Current pharmacokinetic studies in pregnancy do not suggest dose modifications for NRTIs and NVP. Lower than optimal levels of LPV/r and nelfinavir are seen in the third trimester of pregnancy.\textsuperscript{44} Current recommendations suggest that an increase of LPV/r to 533/133 mg BD (or 600/150 mg of the new tablet version, Aluvia) be considered and that nelfinavir should always be dosed as 1,250 mg BD during pregnancy (versus 750 mg TD [three times a day]).\textsuperscript{45,46} EFV is contraindicated in the first trimester due to teratogenicity. The combination of ddI and d4T should not be given in pregnancy due to increased risk of adverse events. Initiation of NVP in pregnancy at CD4 levels above 250 cells/mm\textsuperscript{3} poses a high risk for hepatotoxicity and should be administered only when the benefit clearly outweighs the risk, and under strict monitoring.

**Malaria**

Malaria is one of the leading infectious diseases worldwide. Coinfection of HIV and malaria is common in many areas of sub-Saharan Africa, Southeast Asia, and South America. ARV drugs seem to be safe in the presence of prophylactic anti-malaria regimens such as proguanil (Paludrine), chloroquine, mefloquine, pyrimethamine/dapsone (Maloprim), or atovaquone/proguanil (Malarone). Treatment of malaria with atovaquone/proguanil, dapsone/proguanil, sulfadoxine/pyrimethamine (Fansidar), or mefloquine seems to be safe in persons on ARV drugs. The antibiotics doxycycline, tetracycline, and clindamycin neither affect nor are affected by ARV therapy.

Caution is advised when using quinine, as quinine concentrations in the blood are reduced in the presence of NNRTIs and increased in the presence of PIs. The effect of NNRTIs and PIs on the potency and safety of artemisinins is unclear, so close monitoring of efficacy is required (manufacturer’s summary of product characteristics). Halofantrine is contraindicated with PIs and should be used cautiously with NNRTIs because it is extensively metabolized by CYP3A4, and inhibition could prolong the QT interval, leading to potentially life-threatening cardiac arrhythmia.

Lumefantrine is structurally related to halofantrine; however, it has not been associated with cardiotoxicity. One pharmacokinetic study has evaluated lumefantrine concentrations in combination
with LPV/r. Though lumefantrine concentrations were increased (AUC increased 193%), no EKG changes were observed. Because of the safe profile of lumefantrine, and the association between higher lumefantrine concentrations and malaria clearance, this combination may be considered.67

In contrast to this apparently safe increase in lumefantrine concentrations, another study evaluating amodiaquine and EFV found a significant increase in the amodiaquine AUC (114%–302%) along with significant elevations in the liver function tests. Therefore, amodiaquine should be avoided with EFV and should be used cautiously with PIs until the mechanism of this interaction can be evaluated.48

**Alternative Therapies/Herbal and Traditional Medicine**

A few natural compounds, such as garlic and echinacea,49 have been implicated in ARV drug interactions and should be used with caution. Grapefruit juice has been shown to inhibit CYP activity in the intestine and was thought to be able to boost saquinavir levels50; however, the effect on treatment response is clinically insignificant. As mentioned above, the herbal therapy St. John’s wort is contraindicated with PIs and NNRTIs, as it has been shown to decrease ARV concentrations.

The use of traditional medicines and practices is widespread in many parts of the world. Often, belief in these practices is stronger than reliance on Western medications. As the content of traditional remedies is rarely known, it is extremely difficult to predict any interaction with modern medications. It is therefore very important to inform and educate patients on the unknown but potentially hazardous effects that traditional medicines might have on ART or on therapy for opportunistic infections. Clinicians should also consider a potential interaction between traditional or herbal medications and ARVs when unexpected treatment responses (either suboptimal viral suppression or toxicity) are observed.

**MANAGEMENT OF DRUG INTERACTIONS**

The list of interactions involving ARV drugs is extensive and constantly expanding. To minimize the risk of drug interaction, awareness and vigilance are essential. Prescribing health-care providers need to review the patient’s complete drug history at each visit, and potential drug interactions should be a prime consideration when changing or adding new drugs. Likewise, patients need to understand the importance of informing the healthcare worker about all medicinal products they are using, including traditional medicines and nonprescription drugs. Drug interactions should always be considered as a potential cause in the event of treatment failure or unusual or severe side effects.

For management of serious adverse events, refer to the chapter entitled “Recognition and Management of Antiretroviral Toxicities in Adults”.

Monitoring of ARV treatment efficacy should follow locally adapted guidelines. Determination of drug serum levels (e.g., antiepileptic or anticoagulant drugs) could play a role in specific clinical situations. It is hardly possible to know all possible interactions or to keep up with the increasing list of interactions, but basic knowledge of metabolism of the major drug classes, possible interactions, and available drug interaction references is essential. Detailed information for an individual case can be obtained from online databases such as those from the University of Liverpool1 or the University of California, San Francisco,2 or from paper-based drug interaction charts that are updated frequently.

BEGINNING IN 2002 AND ON A LARGER scale since 2004, antiretroviral therapy (ART) treatment programs have been rolled out in public-sector health facilities in sub-Saharan Africa, the region of the world most affected by the AIDS pandemic. In January 2002, ART became available in Botswana in public-sector health facilities through the national antiretroviral (ARV) treatment program, Masa. *Masa* means “new dawn” in Setswana. The first national public site was at the outpatient Infectious Disease Care Clinic (IDCC) at Princess Marina Hospital, the largest referral hospital in the capital city of Gaborone. The Masa program now provides public ART to more than 100,000 people at more than 32 designated national outpatient treatment sites. Similar programs have been implemented in other regions and countries supported by the World Health Organization (WHO) and the President’s Emergency Plan for AIDS Relief (PEPFAR).

The current international standard recommendation for first-line ART in adults consists of two nucleoside reverse transcriptase inhibitors (NRTIs) plus one non-nucleoside reverse transcriptase inhibitor (NNRTI).\(^1\,^3\) Protease inhibitors (PIs) are reserved for second-line treatment, as needed, due to issues of cost, dosing frequency, drug-drug interactions, potential for long-term side effects, and higher pill burden.

In resource-rich settings, the current gold-standard first-line ART regimen is tenofovir (TDF) plus emtricitabine (FTC)—co-formulated as Truvada—with the NNRTI efavirenz (EFV, or Sustiva), or, more recently, these three ARV medications combined into one tablet per day, namely Atripla. In multiple adult head-to-head clinical trials, ARV-treated individuals receiving the NNRTI EFV (previously with zidovudine [AZT/ZDV] plus lamivudine [3TC] co-formulated as Combivir, and more recently with Truvada) have experienced the most favorable immunologic and virological outcomes. In sub-Saharan Africa, the vast majority of ART-treated persons receive either stavudine (d4T) and 3TC or AZT and 3TC with either nevirapine (NVP) or EFV. Persons failing these first-line regimens are then typically offered the PI lopinavir/ritonavir (Kaletra/Aluvia) with two different NRTIs. Table 1 lists the ARVs currently available for use in resource-limited settings.

The major ARV-associated toxicities seen among ART-treated adults in resource-limited settings are very similar to those reported in the United States and Western Europe among HIV-1 subtype B-infected adults. For discussion purposes, ARV-associated toxicities will be broken down into categories, and the definitions will be based on two factors: (a) usual time of onset (“short-term” or “long-term”) and (b) severity (“mild/moderate” and “severe”). For severity grading, we will use the most current
Short-term toxicities: Short-term toxicities will be defined as those ARV-associated toxicities that occur within the first three to six months following ART initiation.

Long-term toxicities: Long-term toxicities will be those ARV-associated toxicities that occur more than six months after ART initiation.

In summary, we will use the following guiding principles when estimating the grade of severity of signs and symptoms:

- **Mild**: Transient or mild discomfort; no limitation in activity; no medical intervention/therapy required.
- **Moderate**: Mild to moderate limitation in activity, some assistance may be needed; no or minimal medical intervention/therapy required.
- **Severe**: Marked limitation in activity, some assistance usually required; medical intervention/therapy required, hospitalization possible.
- **Life-threatening**: Extreme limitation in activity, significant assistance required; significant medical intervention/therapy required, hospitalization or hospice care probable.

Note: For all laboratory-related toxicities, we will use the Adult DAIDS grading scale (December 2004).4

For each category, we will also describe how best to recognize and manage these toxicities, some of which may be life-threatening.

**Key Definitions and Concepts**

- **Side effect**: Side effects are usually self-limited and not life-threatening, and usually resolve over a short period of time and with symptomatic support. Side effects typically occur early after ARV initiation.

- **Toxicity**: The term toxicity carries with it a more “severe” meaning, as toxicities can be life-threatening and may occur anytime following ART initiation.4

---

4To maintain consistency and uniformity in this text, we have decided to use the term toxicity when referring to any and all ARV-associated events.
of 23.8% (95% CI, 15.5%-31.2%); and 47 of the 153 (30.7%) having treatment-modifying toxicities, with a Kaplan-Meier estimate of developing a treatment-modifying toxicity by year one of 32.2% (95% CI, 23.0%-40.4%). The study also found that 29% of these treatment-modifying toxicities were for severe peripheral neuropathy, 6% for hepatotoxicity, and 4% for ddI-related pancreatitis and NVP-related cutaneous hypersensitivity.

Additional preliminary regional data from Botswana evaluating 306 ART-naive adults treated with PI-sparing public ART as per existing national ARV treatment guidelines (Combivir/NVP [48%] and Combivir/EFV [52%]) showed that 8.0% developed severe (grade 3-4) anemia (mean time to development = 11.6 weeks), 2.7% developed Stevens-Johnson syndrome (mean time to development = 28.0 days on ART), and 3.4% developed grade 3-4 liver function test (serum SGOT/AST and/or SGPT/ALT) abnormalities (mean time to development = 12.6 weeks). This initial group of ART-treated patients was quite ill at the time of ART initiation, with a median CD4 cell count of 81 cells/mm³, with a median plasma HIV-1 RNA level of 442,000 copies/mL, and with 89.2% having WHO clinical stage 3 or 4 disease at the time of ART initiation.

Longer-term ART outcomes data from Khayelitsha, South Africa, have shown similar toxicity rates from 287 adults with advanced baseline HIV-1 disease (median CD4 cell count of 43 cells/mm³; mean log₁₀ HIV RNA of 5.18 copies/mL) treated with Combivir-based ART with either EFV (60%) or NVP (38%). In this cohort, the cumulative probability of changing a single ARV medication by 24 months was 15.1% due to toxicity or contraindications, and 8.4% due to toxicity alone. Most changes occurred soon after ART initiation (median time 42 days; interquartile range 28-56 days). Additional data from this same cohort showed that by 24 months on therapy, similar proportions of patients had switched from d4T, AZT, and NVP due to toxicity (8.5%, 8.7%, and 8.9%, respectively). In contrast, only 1.7% had switched from 3TC. Most drug regimen changes (36 of 44, or approximately 82%) were attributable to anemia among AZT-treated patients.

Data from Uganda (n = 137) among adults receiving d4T- and 3TC-based ART with primarily NVP (77%) or EFV (14%) showed that 55% of patients experienced some level of discomfort, while reporting pain, numbness, tingling of the hands or feet, or skin rash with dryness or pruritus (51%). Rash was reported in 49% of the 125 patients treated with an NNRTI-containing regimen.

Data from 1,000 patients in Haiti treated primarily with AZT and 3TC with either EFV (47%) or NVP (42%) showed that 25% of ART-treated patients required a change in their first-line regimen, with 11% changing for reasons of toxicity. Anemia (5%), central nervous system (CNS) side effects (6%), and rash (3%) were the most common, with two patients developing Stevens-Johnson syndrome, one of whom died. Overall, less than 1% of NVP-treated patients developed hepatitis.

Longer-term data from a large cohort of ART-treated adults in Botswana receiving primarily the dual NRTI combination of ZDV/ddI, ZDV/3TC, or d4T/3TC with either NVP or EFV (n = 650 total) showed that 17.7% of patients experienced a treatment-modifying toxicity, with the most common toxicities being anemia (3% of all patients in the cohort), lipodystrophy (3%), grade 3 hypersensitivity cutaneous reactions or Stevens-Johnson syndrome (3%), neutropenia (2%), lactic acidosis (1.0%), moderate to severe symptomatic hyperlactatemia (1%), hepatotoxicity (1%), neuropsychiatric symptoms (1%), and pancreatitis (1%).

Preliminary data from southern Africa have shown differences in the patterns and rates of toxicities among HIV-1 subtype C-infected adults when compared to HIV-1 subtype B-infected, ART-treated counterparts in resource-rich settings.
Preliminary regional data have reported higher than expected rates of lactic acidosis (1.0%-1.1%) among ART-treated adults, with expected rates from Western literature in the range of 0.1%-0.4% among ART-treated cohorts. The development of lactic acidosis in sub-Saharan Africa appears to be related to female gender, body habitus (being overweight, body mass index > 25 or body weight > 75 kilograms), and use of one or more “D” drugs (d4T and/or ddi). Reasons for this remain to be fully elucidated but most likely involve host genetic differences. More in-depth studies are under way and additional ones are planned. Early on (2002-2004) in public-ART-treated cohorts, there were significant rates of AZT-associated anemia, as high as 8%. Anemia can pose a significant problem, especially in more remote areas where patients have to travel long distances to reach a district or referral hospital and where blood supplies are scarce. Preliminary data have also shown that ART-treated adults appear to have higher than expected rates (as high as 2.7%) of NVP-associated cutaneous hypersensitivity reactions (Stevens-Johnson syndrome) and lipodystrophy.8,13,15

Rates of lipid abnormalities, defined as cholesterol and triglyceride elevations, are not yet known, as few patients have received PI-based ART for prolonged periods of time, although patients can certainly have lipid elevations from d4T or EFV. ART-treated adults, the majority of whom are female in sub-Saharan Africa, are experiencing significant rates of body habitus changes—namely lipoatrophy involving the buttocks, thighs, and face—especially those who have been on ART for more than two years. These body habitus changes have been attributed to d4T use and, along with the higher than expected rates of lactic acidosis, have prompted many policymakers to reconsider first-line ART options for their public ART programs. Public ART programs have already begun to move away from d4T- and AZT-based ART regimens and are switching to TDF (Truvada)-based first-line ART regimens with more favorable tolerability profiles. Certainly, longer-term data on the risk for renal insufficiency and bone porosity changes related to TDF are needed to better inform policymakers. Cost still remains a significant issue, but progress has been made with pharmaceutical corporations and involved foundations (e.g., the Clinton Foundation) working diligently to negotiate more favorable drug access prices.

**MAIN MILD/MODERATE SHORT-TERM TOXICITIES**

**AZT**

The main short-term mild/moderate toxicities experienced among AZT-treated patients are gastrointestinal (GI) problems (nausea, with or without emesis) and headaches. In the majority of cases, these side effects occur within the first few weeks to one month on treatment and resolve on their own without the need for treatment holds and/or substitutions. A small percentage of patients, especially those taking AZT-based ART for postexposure prophylaxis, may need to discontinue their AZT and change to d4T, ddi, or TDF. Neutropenia is a short- to medium-term toxicity associated with AZT due to its effect on myeloid precursors. As persons of African descent have lower total lymphocyte counts (1,500 compared to 2,500 elsewhere), the development of neutropenia is not as clinically significant in sub-Saharan Africa, and there are no studies to determine what absolute neutrophil count (ANC) best correlates with heightened risk for infections. AZT-treated patients who develop neutropenia will typically do so within the first two to six months following ART initiation, and in the vast majority of cases these patients are completely asymptomatic. Mild/moderate decreases in the ANC are of minimal significance and should result in ARV medication switches (to d4T or TDF) only if the ANC is less than 500 cells.
x 10^3 microliters. Persons with moderate decreases in their ANC (ANC values 500 to 750) may have their AZT doses reduced from 300 mg twice daily to 200 mg twice daily and have their ANCs monitored over time. Patients must receive education and counseling on the risk of infections and be told to call or go to the clinic if they develop persistent fevers or any other signs or symptoms of suspected significant bacterial infection.

One additional short- to medium-term potential side effect of AZT therapy is hyperpigmentation. Hyperpigmentation can be caused by other processes or medications but has been seen among AZT-treated patients. It occurs mostly in the nail beds of fingers and toes but may also involve darkening of the mucosal surfaces (oropharyngeal mucosa). No medical therapy or intervention is required.

**d4T and ddI**

The most common short- to medium-term toxicity associated with the “D” drugs (d4T more than ddI) is the development of peripheral neuropathy (PN), namely paresthesias and burning in a stocking-glove distribution, typically involving the feet only. Persons experiencing this ARV-associated toxicity must be monitored very closely, and if PN progresses, drug regimen changes are often indicated. Patients with moderate PN can be managed by treatment with a tricyclic antidepressant (amitriptyline, initial dose 25-50 mg at bedtime but can be increased to 100-150 mg) or ideally neurontin (gabapentin) at an initial dose of 400 mg twice a day and increasing up to 1,600-2,000 mg total per day, as needed. In addition, patients can be given nonsteroidal anti-inflammatory agents (ibuprofen/Motrin [Brufen]) and vitamin supplements (multivitamins and folic acid), but there are no randomized clinical trial outcomes to provide evidence-based benefits of such adjunctive measures in the treatment of PN. One other possible management strategy for patients experiencing moderate PN is to dose-reduce their d4T, but results are inconsistent for the majority of cases. Patients with progressive PN symptoms do best when their d4T and/or ddI is switched to an alternative NRTI such as TDF or ABC.

(Note: AZT can also cause PN, but to a lesser degree than the “D” drugs. Also, PN can be caused by the HIV virus itself, so it is imperative to ask and to document the presence [or absence] of mild/moderate PN prior to ART initiation. TB preventative therapy with isoniazid can also cause PN, even in patients receiving concomitant therapy with vitamin B6 [pyridoxine] given in an attempt to reduce the likelihood of isoniazid-related PN.)

**EFV**

EFV can cause mild/moderate CNS toxicities, with the majority of these toxicities occurring within the first two to four weeks following EFV-based ART initiation. The vast majority (more than 90%-95%) of these mild/moderate CNS side effects are self-limiting and completely resolve within one month on treatment. Rarely do these CNS side effects persist beyond one month of treatment or intensify, necessitating an ARV substitution to NVP. If contraindicated, a PI such as lopinavir/ritonavir (Kaletra/Aluvia) may be substituted instead. The major mild/moderate CNS side effects seen are the following: sleep disturbances, including vivid dreams, nightmares, and insomnia; dizziness, lethargy, or fatigue due to insomnia or reduced sleeping; decreased or increased libido; and euphoria.

**MAIN SEVERE SHORT-TERM TOXICITIES**

**AZT**

The most serious and potentially life-threatening short-term complication related to AZT treatment is anemia. AZT can affect bone marrow progenitor cells and, as a result of its myelosuppressive effects, it can affect all marrow cell lines and can cause
neutropenia, anemia, and thrombocytopenia. In rare cases, idiosyncratic reactions resulting in pancytopenia have been reported. AZT-associated anemia typically develops within the first one to four months following ART initiation. Clinical presentation is varied, but the vast majority of patients complain of increased fatigue, weakness, and dyspnea, depending on the percentage loss of red blood cell mass or volume and the extent to which oxygen-carrying capacity is affected. Patients often have scleral pallor and may have a holosystolic cardiac “flow” murmur (I-III/VI) heard best over their left lower sternal border. For screening purposes, all adults treated with AZT-based ART should have a baseline full blood count performed and should not be initiated on AZT if their baseline hemoglobin (Hgb) is less than 8.0 grams/dL (or less than 7.0-7.5 grams/dL in some settings, depending on existing national ARV treatment guidelines). In addition, patients should receive extensive counseling and education on signs and symptoms that may be suggestive of underlying anemia and should be advised to go to the clinic or contact their treating care provider if any suggestive signs or symptoms of anemia develop. AZT-treated patients should also at a minimum have a full blood count performed at months one and three following ART initiation. If any suspicion of anemia exists at any time during the first four months on ART, then an urgent full blood count should be performed. Some care providers also opt to perform a routine full blood count at two months following ART initiation, which may be advisable, especially in regions, such as sub-Saharan Africa, where at least initially large percentages of patients have advanced immunosuppression (CD4 cell counts less than 50-100 cells/mm³) at the time of ART initiation. AZT-treated patients found to have severe anemia, hemoglobin values less than 6.0 grams/dL, and/or a significant percentage drop from baseline (25%-50% or more) need to be urgently hospitalized, transfused the necessary amount of packed red blood cells, and have their AZT switched to d4T, TDF, or ABC. All patients with severe anemia need to have other possible causes of their anemia ruled out: infectious causes such as malaria or acute parvovirus B19 infection (causing pure red blood cell aplasia); GI bleeding (peptic ulcer disease / severe gastritis, variceal bleeding from end-stage liver disease / cirrhosis from underlying hepatitis B or C, alcoholic liver disease, etc.); obstetric/gynecologic causes (ectopic pregnancy, etc.); and/or malignancies (colon carcinoma, etc.). There appears to be no established role for erythropoietin in the acute setting, but some care providers have administered such therapy with favorable outcomes.

**ddI- or d4T-Related Pancreatitis**

Patients treated with ddI as well as d4T (rare) and even 3TC (extremely rare) may develop chemical or clinical pancreatitis. Based on the definitions used by the Adult Clinical Trials Group (ACTG) as per the DAIDS grading scales, chemical pancreatitis is defined as the presence of a grade 3 lipase elevation on at least two determinations obtained within a two-week period. Clinical pancreatitis is graded based on the highest severity level achieved in the description of associated symptoms, which include abdominal pain (typically peri-umbilical), nausea, and/or vomiting. Patients diagnosed as having clinical pancreatitis (grade 3-4) should have their ART held and should be evaluated for other possible etiologies, such as alcohol use/abuse, traditional medication use, concomitant medications that can also cause pancreatitis (pentamidine, cotrimoxazole [rarely], etc.), gallbladder disease, and so on.

**d4T- or ddI-Related PN**

One possible short- to medium-term toxicity associated with the “D” drugs (d4T more than ddI) is the development of PN, namely paresthesia and burning in a stocking-glove distribution, typically involving the feet only. Patients developing severe PN will
normal, ART should be held and patients should be comprehensively evaluated for other possible contributing causes, such as alcohol, traditional or herbal medications, anti-tuberculosis therapy (ATT), and so on. An abdominal ultrasound may also need to be performed to aid in the diagnosis, looking for fatty hepatic infiltration or changes. Once the patient has improved clinically and the liver function tests have returned to normal (or near normal levels—at least less than five times the upper limits of normal), then ART can be reinitiated on a case-by-case basis. Patients should not be reinitiated with the dual NRTI combination of d4T plus ddI, but instead the following dual NRTI combinations should be considered (if they are not contraindicated): ZDV/3TC, TDF/FTC, TDF/3TC, or ABC/3TC.

Abacavir-Related Hypersensitivity Reactions

The most potential severe short-term toxicity associated with abacavir (ABC) use is the ABC hypersensitivity reaction (ABC HSR), which has been reported in up to 5% of ABC-treated patients. ABC HSR can be fatal and is characterized by fever, rash, nausea, vomiting, malaise or fatigue, loss of appetite, and/or nonspecific respiratory symptoms such as sore throat, cough, and dyspnea. These symptoms can be easily confused with influenza-like symptoms, especially during colder periods of the year. The case fatalities have primarily occurred among patients who did not recognize this potential toxicity and therefore did not contact their physicians before they rechallenged themselves with ABC. This potentially life-threatening toxicity may be difficult to distinguish from other intercurrent illnesses such as influenza and viral illnesses and other HSRs such as cotrimoxazole- or NVP-associated cutaneous and systemic reactions. Patients with ABC HSR typically present with acute-onset fever, tachycardia, flushing...
(diffuse erythema—which may be difficult to fully appreciate among persons with darker skin), and hypotension and mimic persons presenting in early septic shock. Patients with NVP- or cotrimoxazole-associated systemic reactions, in contrast, tend to present with fevers and diffuse, clearly visible cutaneous rash and inflammation, which in severe cases typically involve the mucous membranes as well as the trunk and extremities. This potentially life-threatening toxicity typically occurs within the first two to four months following ABC initiation. Studies have shown a significant genetic predisposition to the risk for ABC HSR\textsuperscript{16,17}, namely, persons with the HLA B*5701 allele (and also HLA DR7 and HLA DQ3) are at significantly higher risk for toxicity. Genetic studies have also shown that this allele is more common in Caucasian populations (present in up to approximately 5% of studied Caucasian adults of European descent)\textsuperscript{18,19} and is rare among African American and African populations. The management of ABC HSR is mainly supportive, with the most important component being the discontinuation of ABC. Dispensing staff must collect all dispensed ABC to ensure that persons do not rechallenge themselves with ABC, as rechallenge—that is, failure to recognize the toxicity—has been implicated in all the ABC-associated fatalities reported in the literature.

**NVP-Related Hepatotoxicity**

Hepatotoxicity can be caused by a number of medications and/or substances, including alcohol, anti-TB medications, acetaminophen intoxication, and the majority of PIs, both NNRTIs and NRTIs. NVP has been associated with the development of potentially life-threatening hepatotoxicity, especially during the first 4 to 18 weeks on treatment. Women initiating NVP-containing ART for the first time with baseline CD4 cell counts greater than 250 cells/mm\(^3\) (and men with CD4 cell counts greater than 400 cells/mm\(^3\)) are at significantly heightened risk (up to 10- to 12-fold higher) for the development of serious hepatotoxicity than are those initiating NVP-based ART for the first time with CD4 cell counts less than 250 cells/mm\(^3\). Treatment is largely supportive, with ART being held until liver function tests have normalized or nearly normalized.

**NVP-Related Cutaneous Toxicity**

The most severe forms of NVP-related rashes are known as Stevens-Johnson syndrome, characterized by mucous membrane involvement. If more than 30% of the body surface is involved, it is referred to as toxic epidermal necrolysis (TEN). This rash typically occurs within the first 4 to 16 weeks following NVP-based ART initiation. Females and those of African, Asian, and Hispanic descent appear to be at heightened risk for this potentially life-threatening toxicity. Systemic symptoms include fever, arthralgias, and malaise or fatigue. The rash begins typically as truncal skin eruptions, which can progress to involve mucous membrane surfaces (eyes, genitals, and oropharynx) and may even progress to epidermal detachment and/or skin necrosis that mimics severe body burns. Cotrimoxazole and phenytoin can also cause similarly severe cutaneous reactions. Treatment consists of stopping all ARVs (while considering the administration of a three to five day dual NRTI tail to preserve future EFV use in individuals with moderate [not severe] symptomatology), as well as aggressive wound care, intravenous hydration, antihistamines, parenteral nutrition (if necessary), and antipyretics. The brief use of high-dose corticosteroids for three to five days among individuals with severe Stevens-Johnson syndrome is very controversial, but has been done without appreciable detriment in select Batswana adults.

**EFV-Related CNS Toxicity**

Due to its ability to readily cross the blood-brain barrier, EFV has been associated with numerous CNS toxicities, which typically develop within the
first two to four weeks following initiation. These CNS toxicities include sleep disturbances (insomnia, vivid dreams or nightmares, hallucinations, excessive somnolence), mood disorders (euphoria, mania, decreased or increased libido, and very rarely homicidal or suicidal ideation), and other CNS toxicities such as seizures and dizziness. In the vast majority of cases, these potentially debilitating toxicities are self-limited and resolve with continued treatment by the first month following ART initiation. In select cases, especially those involving persons operating heavy machinery, drivers of commercial transport vehicles (buses, trains, etc.), and airline pilots, a furlough for approximately two weeks following EFV initiation would minimize risk in case these patients develop CNS side effects.

MAIN MILD/MODERATE LONG-TERM TOXICITIES (INCLUDING THOSE TOXICITIES WITH POTENTIAL LONG-TERM COMPLICATIONS)

Fat Maldistribution Syndromes (PIs, EFV, d4T)
Peripheral fat loss (lipoatrophy), manifested as facial, buttocks, and/or thigh thinning, can be very cosmetically unappealing and stigmatizing among involved individuals. This is typically a longer-term complication (i.e., months following ART initiation). Treatment consists of switching to an individual NRTI medication (i.e., TDF or ABC, co-administered with either FTC or 3TC) minimally associated with lipoatrophy. Injectable agents for the treatment of lipoatrophy (poly-L-lactic acid, etc.) are not currently available in the developing world due to high cost.

Increased fat accumulation (lipohypertrophy) involving the abdomen, breasts, and neck (dorsocervical fat pad) have been reported following treatment with EFV and/or the entire class of PIs. Treatment consists of switching to other ARV medications (i.e., PIs less commonly associated with body habitus changes). Response is often slow and may not occur until three to four months following the ARV medication switch.

Nelfinavir-Related Diarrhea
Diarrhea has been reported among nelfinavir (NFV)-treated patients, especially early on in their treatment course. In the majority of cases, this is self-limited and can be managed successfully while continuing NFV by increasing fiber intake and/or by taking calcium supplements.

Indinavir-Related Nephrolithiasis
Anytime following indinavir (IDV)-based ART initiation, persons may develop nephrolithiasis, which manifests as dysuria, hematuria, and rarely as a rise in serum creatinine or acute renal failure. The risk is highest during times of reduced fluid intake. This often debilitating complication has been reported in up to 34% of IDV-treated patients (range: 4.7%-34.4%). Those at risk include patients with a previous history of nephrolithiasis, those with high peak IDV concentrations, and those unable to maintain adequate hydration. Treatment consists of aggressive IV hydration, pain control, and switching the ARV medication to another PI. Stent placement may be required for severe cases.

Insulin Resistance or Diabetes Mellitus (PIs)
Weeks to months following PI-containing ART regimens, patients can develop diabetes mellitus, which clinically manifests as expected—namely, patients present with the following: polyuria, polydipsia, polyphagia, unexplained weight loss, and fatigue or weakness. Case reports of diabetes mellitus have been reported in up to 5% of patients receiving PI-based ART regimens. Baseline fasting blood-glucose levels should be tested for patients about to initiate PIs, and this should be repeated
Symptomatic osteonecrosis has been reported in up to 1.3% of PI-treated individuals. The initial management is conservative and consists of decreased weight bearing on the involved joint or joints and analgesic control, with surgical intervention (core decompression and total joint replacement) reserved for severe refractory cases.

**Hyperlipidemia (PIs)**

All PIs have been associated with the development of hyperlipidemia. Atazanavir/ritonavir (ATV/r), and more so unboosted atazanavir (ATV), have been reported to cause less adverse effects on lipids than the other PIs. Other ARV medications, including d4T and EFV, have also been associated with the development of hyperlipidemia. Typical onset is months following ART initiation. Risk factors include preexisting hyperlipidemia. Patients about to initiate PIs should therefore have a baseline lipid profile (cholesterol, LDL and HDL cholesterol, and triglycerides) performed, and this should be repeated 1 to 3 months following PI initiation and then every 12 months thereafter. Hyperlipidemia increases the risk of large-vessel atherosclerosis, including myocardial ischemia or infarction and cerebrovascular accidents (CVAs). Management includes lifestyle modifications (i.e., diet, exercise, and/or smoking cessation), switching to agents less likely to cause lipid changes, and pharmacologic intervention that may include treatment with lipid-lowering agents such as pravastatin or atorvastatin. Hypertriglyceridemia requiring pharmacologic intervention should be treated with benzafibrate (or fenofibrate), gemfibrozil, or niacin.

**Osteonecrosis (PIs)**

Although occurrences are rare, all PIs have been associated with the development of osteonecrosis. The clinical presentation is nearly identical to that in HIV-negative individuals, in that persons typically present with periarticular discomfort, often brought on while weight bearing or ambulating.
by nonspecific symptoms such as nausea, emesis, weight loss, abdominal pain, and fatigue or weakness. Subsequent symptoms may be more rapid in onset and may include dyspnea, tachycardia, jaundice, muscular weakness, worsening PN, mental status changes, and/or respiratory distress. Some patients may present with multisystem organ failure, such as fulminant hepatic failure, acute pancreatitis, encephalopathy, or respiratory failure. Laboratory findings include decreased serum bicarbonate (< 20 mmol/L), low arterial pH (< 7.30), increased serum lactate (> 5.0 mmol/L), increased LDH, mild to moderate elevations in AST/SGOT and/or ALT/SGPT, elevated amylase and/or serum lipase, and increased anion gap (> 12-14). Management includes the discontinuation of all ART, and supportive care, including mechanical ventilation if needed.

**Rapidly Ascending Neuromuscular Weakness (d4T)**

Rapidly ascending neuromuscular weakness has been reported among persons receiving NRTI-based ART, particularly those receiving d4T and/or ddI. Patients complain of acute onset weakness that mimics Guillain-Barré syndrome and may progress to respiratory paralysis and death. This rare syndrome typically occurs months after ART initiation and may be associated with markedly elevated creatine phosphokinase (CPK) levels, elevated serum lactate levels, and an anion gap acidosis. Treatment involves supportive therapy and discontinuation of ARVs. Mechanical ventilation can be instituted, if needed. Other treatments to consider, which have had variable success rates and outcomes, include plasmapheresis, high-dose corticosteroids, intravenous immunoglobulin (IVIG), and L-carnitine.

**ddl-Related Pancreatitis (Also Possible from d4T and/or 3TC)**

Pancreatitis may develop in one of two forms: chemical or clinical pancreatitis. Chemical pancreatitis is defined as the presence of a grade 3 lipase elevation on at least two determinations obtained within a two-week period. Clinical pancreatitis is graded based on the highest severity level achieved in the description of associated clinical symptoms. The diagnosis is based on the presence of clinical symptoms (using the DAIDS/ACTG toxicity grading scale): nausea, vomiting, and/or abdominal pain (typically periumbilical) plus a confirmed grade 3 lipase elevation plus (for persistent symptoms and/or persistent lipase elevations to grade 1-2 levels) radiographic evidence of pancreatic inflammation or edema on an abdominal ultrasound and/or abdominal computed tomography (CT) scan. Clinical pancreatitis may be life-threatening and has been associated with d4T and/or ddI use in adults and 3TC use in children (very rarely adults). Clinical pancreatitis may develop two or more months following ART initiation, and persons on d4T and/or ddI need to be monitored closely for the development of GI symptoms (i.e., abdominal pains, nausea, and/or emesis). Other risk factors for pancreatitis include alcohol use/abuse, hypertriglyceridemia, a previous history of pancreatitis, and the use of TDF plus ddI without the ddI dose reduction to 250 mg. Diagnosis is made by checking a serum lipase and by abdominal imaging study (abdominal ultrasound and/or abdominal CT scan). Patients with confirmed clinical pancreatitis should have their ART held, and, once they are stabilized, their NRTIs should be switched from d4T and/or ddI to TDF/FTC, TDF/3TC, or ZDV/3TC.

**d4T- or ddI-Related PN**

One possible severe toxicity associated with the “D” drugs (d4T more than ddI) is the development of PN, namely paresthesia and burning in a stocking-glove distribution, typically involving the feet only. Patients developing severe PN will also by definition have difficulty ambulating and/or sleeping, due to the severity of their paresthesia, and discomfort will significantly impair their ability to perform the
activities of daily living. The vast majority of ART-treated patients developing grade 3-4 PN should have their treatment modified. Patients with severe PN need to have their d4T and/or ddI switched to an alternative NRTI such as TDF or ABC. (Note: Such patients should be told that it may take several [two to four] months following their ARV medication switch before they experience any significant improvement in these often debilitating symptoms.)

**Bleeding Episodes (Increase in Hemophiliac Patients)**

Although occurrences are rare, PI-treated hemophiliac patients, within the first few weeks following ART initiation, can develop spontaneous bleeding as manifested acutely by bleeding into joints, soft tissues, and muscles. Treatment consists of switching to an NNRTI, and acutely affected patients may require factor VIII products.

**Nephrotoxicity (IDV, Possibly TDF)**

In the literature, there are case reports of IDV- and TDF-associated nephrotoxicity leading to renal insufficiency or failure. Patients are often asymptomatic, so patients at heightened risk for renal insufficiency (history of renal insufficiency, underlying renal disease, etc.) should be given IDV or TDF only if the benefit clearly outweighs the risk of treatment.

All patients should have their creatinine clearance calculated using the Cockcroft-Gault method prior to TDF initiation, and patients should be monitored for worsening renal function, especially during the first six months on treatment. Patients often present completely asymptptomatically, and cases of TDF-induced Fanconi syndrome have been reported. Their diagnosis requires urine microscopy plus phase or Millipore analysis. Patients having a creatinine clearance of less than 60 cc/minute should not initiate TDF, and all TDF-treated patients should ideally have their creatinine clearance measured at least every six months and more frequently if they appear to be at heightened risk for nephrotoxicity (i.e., older than age 60, having preexisting renal insufficiency/disease, being on or having recently received other potentially nephrotoxic medications [e.g., amphotericin B], and/or having diabetes mellitus or poorly controlled hypertension).

IDV-treated patients may develop renal insufficiency or failure caused by partial or complete urinary obstruction due to the development of IDV-induced nephrolithiasis. Diagnosis can be made by urine microscopy and renal ultrasound (hydrenephrosis); treatment consists of IDV discontinuation and supportive care, including IV hydration and pain management.

**Risk for Myocardial Infarction (Possibly ABC More Than ddI)**

Attention has focused primarily on the role of PIs and the risk of myocardial infarction (MI). However, recent data presented at the Fifteenth Conference on Retroviruses and Opportunistic Infections (CROI) from the D:A:D (Data Collection on Adverse Events of Anti-HIV Drugs) collaborative cohort study unexpectedly showed that recent use of ABC and ddI was associated with an increased risk of MI, by 90% and 49%, respectively. The excess risk of MI associated with ABC and ddI use was most significant—in absolute terms—among patients with high underlying cardiovascular risk. Preferential use of ABC and ddI in patients with an a priori increased cardiovascular risk appears not to explain these unexpected findings. Certainly, more intensive longer-term follow-up is needed, but in HIV-1 infected adults with multiple risk factors for coronary disease (high cardiovascular risk), physicians may opt to prescribe alternative NRTI combinations, avoiding ABC and/or ddI in such patients until additional long-term, and ideally randomized clinical trial data, become available.
CONCLUSION

In summary, ARV medications are very well tolerated with minimal toxicities in the vast majority of ART-treated adults. However, potentially life-threatening short- and long-term toxicities can occur and require that all involved healthcare personnel carefully and consistently educate their patients to improve the recognition and significantly reduce the likelihood of adverse outcomes. Toxicity profiles preliminarily appear to differ in the developing world when compared to Western European and North American cohorts. Additional in-depth research is clearly warranted.

Between 10% and 40% of individuals initiating combination antiretroviral therapy (ART) for HIV-1 infection experience an immune reconstitution inflammatory syndrome (IRIS), also known as immune reconstitution disease. 1-7 IRIS is caused by immunological responses resulting from the immune system’s renewed activity against latent pathogens or other antigens. Although extensively described in the literature, IRIS lacks a universally recognized case definition because of its diverse clinical spectrum and the difficulty in clearly differentiating the syndrome from other conditions, such as drug toxicity or new opportunistic infections (OIs).

Epidemiology and Clinical Spectrum

A wide range of infectious and noninfectious forms of IRIS has been reported, as summarized in Table 1.

“Paradoxical” and “Unmasking” IRIS

IRIS may present as two distinct clinical scenarios (see Box 1) with different clinical features and differential diagnoses. “Paradoxical” IRIS occurs when a patient with a previously diagnosed OI or malignancy experiences a deterioration in clinical status after the initiation of ART, usually despite effective treatment of the underlying OI. Similar reactions have been described in HIV-negative patients receiving antituberculous therapy (ATT) 8 and may be indistinguishable from ART-induced IRIS. However, higher rates of paradoxical reactions are reported in patients receiving both ART and ATT (incidence of 28% to 36%) than in those treated for TB alone (2% to 10%). 9 Worldwide, the most common and clinically significant paradoxical forms of IRIS are those associated with TB and cryptococcal disease. In seven cohort studies of

patients with known TB initiating ART, the incidence of paradoxical TB IRIS ranged from 7.6% to 43%.9,48-53 The incidence of cryptococcal paradoxical IRIS in three studies of patients on treatment for cryptococcal disease who subsequently initiated ART was 8.3% to 33.9%.20,49,54

“Unmasking” IRIS occurs when an OI develops in a patient who before starting ART did not manifest the condition. In this situation, subclinical or undiagnosed OIs are “unmasked” by the emergence of pathogen-specific immune responses. Unmasking IRIS has been much less well described than paradoxical IRIS, and its incidence varies according to the underlying distribution of various pathogens in the population, and by the level of screening for OIs before the initiation of ART. For example, the use of routine chest X-rays and sputum smear examination for acid-fast bacilli (AFB) in both symptomatic and asymptomatic patients increases the ascertainment and treatment of TB prior to ART initiation.

Incidence of IRIS
Four retrospective cohort studies from South Africa, Europe, and Australia have reported on the incidence and clinical spectrum of IRIS in all patients starting ART (Table 2). Cumulative incidence ranged from 10.4% to 25%, and rates ranged from 5.8 to 51.5 per 100 person-years (PYs). The median time to the development of IRIS was 7 to 20 weeks, with more than half of events occurring within the first three months of ART. Of 201 IRIS cases reported in the four cohort studies, the most common pathogens associated with IRIS were varicella zoster virus (42 cases [21%]), herpes simplex virus (35 cases [17%]), Mycobacterium tuberculosis (31 cases [15%]), hepatitis C virus (16 cases [8%]), and human papillomavirus (13 cases [6%]). Their relative incidence in different studies partially reflects the characteristics of the study populations in terms of the underlying prevalence of infections in various geographic settings, the level of immunosuppression, the type of HIV risk exposure (e.g., a higher prevalence of hepatitis B and C coinfection among injecting drug users), and level of screening for underlying OIs in the clinic population.

Other cohort studies of the epidemiology of IRIS have included only patients receiving treatment for specific OIs and have estimated the incidence of IRIS related to those OIs. There are six published studies of patients with TB (from the United States, India, Spain, France, South Africa, and Thailand); two studies of patients with cryptococcosis (France and the United States); and one study of patients with either TB, cryptococcosis, or Mycobacterium avium complex (MAC) infection (the United States). The incidence of IRIS in the TB cohorts ranged from 7.6% to 36%, with rates from 13.6 to 31.6 per 100 PYs, and the incidence of cryptococcal IRIS ranged from 8.3% to 33.9%, with rates from 4.2 to 17.9 per 100 PYs. The single study of IRIS secondary to MAC infection found an incidence of 31.4% and a rate of 15.1 per 100 PYs. A higher incidence of IRIS was observed in patients with TB initiating ART in high-resource settings compared with resource-limited settings (35% to 43% versus 7.6% to 12.6%, respectively). Reasons for these differences include a shorter time between diagnosis of OI and ART initiation in high-resource settings, and varying intensity of clinical surveillance during follow-up.

Clinical Features
Almost any organ or system may be affected by IRIS, and the clinical features depend on the site affected, the pathogen involved, and the host-parasite interaction. The clinical spectrum of IRIS in a cohort in Durban is summarized in Figure 1, and presentations of the most common and important IRIS syndromes are described in the following sections.

Tuberculosis and MAC
IRIS in response to M. tuberculosis infection is probably the most common and clinically significant form of IRIS, as well as the most extensively described in case reports and cohort studies. TB IRIS may present as unmasking or paradoxical IRIS, and presents with various clinical manifestations dependent on the site of disease. It accounts for approximately one-half of the HIV-related IRIS events in resource-limited settings where HIV/TB coinfection is common. Studies performed in Europe and the United States reported an incidence of TB IRIS among patients with a prior diagnosis of infection (i.e., paradoxical IRIS) varying between 30% and 43%. Only one study provides an estimate of the incidence of unmasking TB IRIS, of around 5% in Johannesburg, South Africa. A detailed review of all species of mycobacterial IRIS summarizes 86 cases of TB IRIS from 27 papers. Among those cases, the most common manifestation was lymphadenopathy (71% of cases), with or without overt lymphadenitis. Pulmonary disease was

also common, occurring in 28% of reported cases. On radiological imaging, increased pulmonary infiltrates, pleural effusions, mediastinal lymphadenopathy, and tracheal compression have been reported. Other manifestations include ascites, focal abscesses, hypercalcemia, and central nervous system (CNS) lesions (including tuberculosis). A case definition of both paradoxical and unmasking TB IRIS has recently been developed (see Box 2), although this now requires validation in different practice settings.

Although MAC IRIS is well described, the significance of the infection is eclipsed by TB in resource-limited settings. Clinical presentations of MAC IRIS in patients with advanced disease tend to be atypical, with focal rather than disseminated infection. For example, lymphadenopathy was seen in 69% of reported cases (44 of 64), also with pneumonia, pyomyositis, and soft tissue infections.

Two cases of unmasking TB IRIS from the authors’ clinical practice are briefly presented here. The first is a patient with a baseline CD4 lymphocyte count of 79 cells/mm³ and a history of oral thrush but no other OIs. A chest X-ray just prior to ART initiation showed no signs of TB. After about eight weeks of ART associated with a CD4 count increase to 142 cells/mm³, she developed a mass in the left axilla, which subsequently started to discharge purulent material (Plate 1). Ziehl-Neelsen staining of the pus revealed AFB, typical of TB. The second case was a patient with
Cryptococcal disease is the most common fatal CNS infection in late-stage HIV patients in sub-Saharan Africa and, after TB, is the most common serious form of IRIS in resource-limited settings. Between 8% and 43% of patients with cryptococcal disease who are treated with ART exhibit a paradoxical deterioration due to IRIS, with the most common manifestations being aseptic meningitis. A CD4 count of 68 cells/mm³ who was diagnosed with a bacterial meningitis. Investigations for TB were negative (Plate 2a), and one month after recovery, the patient was started on ART. Two weeks later she developed night sweats, and after a further two weeks, cough and weight loss. A chest X-ray revealed right-upper-lobe consolidation (Plate 2b), and sputum was AFB smear positive.

meningitis, increased intracranial pressure (ICP), development of intracranial cryptococcomas, and lymphadenitis. In the majority of individuals, these symptoms develop despite apparent antifungal treatment success as evidenced by sterile fungal cultures. Although a detailed review of 25 reported cryptococcal IRIS cases found that more than half (56%) presented with lymphadenitis or sterile abscesses, most cryptococcal IRIS reported in the literature manifested as CNS disease. Pulmonary, ocular, breast, and soft tissue involvement have also been described (Plate 3). Since lymphadenitis and soft tissue swellings may be clinically indistinguishable from other OIs, such as mycobacterial infection, it is important to examine and culture material aspirated from the lesions.

We report an illustrative case from clinical practice. A 34-year-old Ugandan woman with a CD4 count of 9 cells/mm³ was diagnosed with HIV-1 infection and cryptococcal meningitis, and received three weeks of amphotericin therapy prior to ART initiation. Two weeks later, the patient presented with symptomatic raised ICP characterized by papilledema and a visual field defect. She experienced a good clinical response, with a reduction in her cerebrospinal fluid (CSF) cryptococcal antigen (CRAG) titer from 1:640 to 1:20, and conversion of her CSF fungal culture from positive to negative, while the CSF protein rose from 290 mg/L to 535 mg/L and the CSF white cell count remained unchanged at less than 5 cells/mm³. However, this case illustrates that although cryptococcal IRIS of the CNS is often described as associated with an increased CSF leukocyte count, protein, and opening pressure, these features are too inconsistent for use in confirmation of IRIS and exclusion of the alternative diagnosis of failure of antifungal therapy. In this case, strong evidence in support of a diagnosis of IRIS was the negative India ink stain and fungal cultures in the presence of persistently positive CSF CRAG, and clinical evidence of recurrent meningitis.

Kaposi’s Sarcoma
Published data on Kaposi’s sarcoma (KS) IRIS are limited largely to case reports, but recent conference abstracts have highlighted an increasingly important role for this phenomenon in sub-Saharan Africa. Around two-thirds of all patients with KS prior to ART initiation may develop subsequent paradoxical KS IRIS, although rates of unmasking KS IRIS have yet to be quantified. Risk factors specific to KS IRIS include higher levels of pre-ART quantitative human herpesvirus 8 (HHV-8) viral load (VL). The clinical spectrum is highly variable in both characteristics and severity, including swelling, tenderness, and inflammation of cutaneous and visceral lesions, expansion of pleural effusions, deterioration in parenchymal lung disease, and worsening lymphedema. Fatalities have been described. In the authors’ own practice, the rapid and massive enlargement of both palatal and pulmonary lesions in one patient led to acute fatal respiratory failure.

Inflammatory Dermatoses
In an observational cohort in Durban, South Africa, dermatological conditions were the most frequent manifestations of IRIS, occurring in about 11% of all patients initiating ART (unpublished data). Of dermatological IRIS, itchy folliculitis and papular pruritic eruptions accounted for around 60% of all IRIS events. The typical appearances of itchy facial folliculitis (Plates 4a to 4c) affect mainly the face, trunk, and proximal upper limbs. The histological entities of eosinophilic, neutrophilic, lymphocytic, and mixed folliculitis may be clinically indistinguishable, and may present either as paradoxical IRIS, with a rapid worsening in the setting of previously stable or mild disease, or as an unmasking event, presenting for the first time shortly after initiating ART. The condition is usually itchy, and
disfiguring hyperpigmentation may result. Other dermatological manifestations of IRIS include warts, molluscum contagiosum, papular pruritic eruption, and tinea.\textsuperscript{30,47,55}

**Herpes Simplex and Varicella Zoster Virus**
Herpes simplex virus (HSV) and varicella zoster virus (VZV) infection are common in patients living with HIV. Although sustained ART-related improvements in immune function should ultimately reduce the burden of both diseases, patients frequently present with these clinical events within the first three months of ART.\textsuperscript{25,28,29} Such cases may present as the first manifestation of shingles or genital herpes in a patient recently started on ART (unmasking), or as a more florid expression of disease in someone with previous symptomatic disease (paradoxical). In most resource-limited settings, there is ubiquitous exposure, with seroprevalence of VZV and HSV-1 in adults approaching 100%, making new acquisition of infection after ART initiation unlikely. Plate 5 shows an example of oral herpes due to HSV-1 infection presenting for the first time in a 39-year-old adult who had started ART four months previously. The CD4 count had risen from 81 cells/mm\(^3\) at baseline to 108 cells/mm\(^3\) when the lesions appeared.

**Chronic Viral Hepatitis**
Distinguishing IRIS from other causes, such as drug toxicity or reactivation of hepatitis B or C, can be very challenging. Elevation of transaminases following initiation of ART is common, affecting up to 18% of patients.\textsuperscript{69,70} In addition, associated symptoms, such as fatigue, abdominal pain, vomiting, and jaundice, are nonspecific.\textsuperscript{26,27} Features that are more suggestive of IRIS are a lack of a rise in hepatitis B DNA, and conversion from e-antibody negative to positive. However, such tests are unlikely to be available in most resource-limited clinical settings.

**Risk Factors for IRIS**
Despite a lack of universal agreement on risk factors, a general consensus has emerged that patients with more advanced immunosuppression (i.e., those with lower CD4 count and higher VL prior to ART) and those with greater pathogen burden (indicated by disseminated disease, higher cryptococcal antigen titer, and indirectly by a shorter duration of OI therapy) are at a greater risk of IRIS.

Four published cohort studies of IRIS in all patients starting ART have examined potential risk factors for IRIS. The most consistent finding has been an association with a lower baseline CD4 cell count or CD4 percentage at ART initiation,\textsuperscript{22,30,55,56} with a hazard ratio of 1.39 for each 50 cells/mm\(^3\) decrease in baseline CD4 count in one study.\textsuperscript{56} Two other studies found odds ratios (ORs) for IRIS in patients with a baseline CD4 count below 100 cells/mm\(^3\) of 2.5 (95% confidence interval [CI], 0.9-6.4) and 3.1 (95% CI, 1.2-8.0) when compared with patients with higher CD4 counts.\textsuperscript{22,55} This may reflect the higher burden of viral or other pathogens or the increased susceptibility to immune dysregulation during immune reconstitution with more advanced immunodeficiency.

Other immunological risk factors include a baseline CD4 percentage of less than 10% (OR 3.0; 95% CI, 1.2-7.6) compared with a percentage greater than 15%,\textsuperscript{55} a baseline CD8 percentage greater than 65% compared with less than 52% (OR 3.1 on bivariate analysis; 95% CI, 1.2-7.6),\textsuperscript{55} and an increase in CD4 count at 12 weeks of less than 69 cells/mm\(^3\) compared with greater than 133 cells/mm\(^3\) (OR 2.6; 95% CI, 1.0-6.6).\textsuperscript{55} A final CD4 count greater than 400 cells/mm\(^3\) was a protective factor compared with patients with lower counts (OR 0.3 on multivariate analysis; 95% CI, 0.1-0.8).\textsuperscript{22} Other factors associated with the development of IRIS include a reduction in VL at 12 weeks of less than 2 log,\(_{10}\) compared with greater than 3 log,\(_{10}\) (OR 0.3; 95% CI, 0.1-0.7),\textsuperscript{55} younger age (median
of 33.7 years at baseline in IRIS cases compared with 35.6 years in controls, \( P=0.021 \), and baseline hemoglobin (10.95 g/dL in cases compared with 12.30 g/dL in controls).\(^71\)

**Patients Coinfected with Other OIs**

The most important risk factor for IRIS in patients with an existing OI in five out of nine cohort studies was shorter time between OI diagnosis and initiation of ART.\(^20,49,50,52,54\) In a South African outpatient setting, the relative risk (RR) for IRIS was 69.5 (95% CI, 9.94-485.6) in patients initiating ART within 30 days and 10.6 (95% CI, 1.88-59.5) in those starting after 31 to 60 days, compared with patients delaying ART more than 90 days.\(^52\) In patients treated for cryptococcosis, those diagnosed with an OI within one or two months of starting ART were at higher risk of IRIS than were patients delaying ART (OR 5.5; 95% CI, 1.0-29.6 and RR 1.7; 95% CI, 1.0-2.3).\(^20,54\)

Three studies also found an association with markers of pathogen burden—namely, cryptococcal fungemia at baseline (OR 6.1; 95% CI, 1.1-35.2),\(^10\) higher CSF cryptococcal antigen titer (1:4096 in patients with IRIS versus 1:1024 in those without IRIS, \( P=0.02 \)),\(^54\) and presence of extrapulmonary TB compared with pulmonary TB (OR 8.2; 95% CI, 1.8-37.9).\(^53\) Other risk factors include HIV diagnosis revealed by cryptococcosis (OR 4.8; 95% CI, 1.0-21.7),\(^20\) ART-naive status (RR 3.87; 95% CI, 1.01-14.88),\(^49\) and a more substantial drop in VL (a 2-log\(_{10}\) decrease in VL at 90 days gave an RR of 3.66 [95% CI, 1.55-8.64] compared with a lesser VL response in one study,\(^49\) and a -2.4 change in log\(_{10}\) VL in patients with IRIS compared with a +0.4 change in controls [\( P=0.02 \) found in another study].\(^50\)

The implications for resource-limited settings are significant. As a result of the global roll-out of ART across sub-Saharan Africa, South America, and southern Asia, large numbers of patients with advanced HIV disease and a high burden of serious OIs are initiating ART. It is therefore anticipated that IRIS will represent a significant problem in these settings, as a result of the increased prevalence of risk factors for IRIS such as high rates of prior OIs, lower baseline hemoglobin, lower CD4 count and percent, lower age at commencement of treatment, and greater pathogen burden.

**Clinical Outcomes**

The clinical outcomes of IRIS have not been well documented. The highest rates of morbidity and mortality are seen in cryptococcal disease. In one reported series, the mortality rate exceeded 50%,\(^60\) although it is unclear to what extent this reflects suboptimal management of the underlying cryptococcal infection. TB IRIS is associated with significant mortality, with reports ranging from 11% of individuals with paradoxical TB IRIS\(^52\) to 16%-25% in unmasking TB IRIS.\(^72,73\) Deaths from IRIS are mainly due to the consequences of raised ICP, widespread pulmonary disease, and lesions in critical anatomical regions such as the brain, spinal cord, and trachea.\(^74,77\) Sight-threatening lesions caused by immune responses against cytomegalovirus (CMV) have also been described.\(^23,24\) Dermatological IRIS is common and may have serious consequences for the patient in terms of symptoms, disfigurement, and general well-being. Although IRIS is often self-limiting, it may be prolonged, painful, or disabling and thus warrants prompt diagnosis and management.

Overall, findings from the ART-LINC (antiretroviral therapy in lower income countries) collaboration across multiple sites in sub-Saharan Africa indicate that IRIS might be a significant cause of death during the first few months of ART in resource-limited settings.\(^78\) Mortality was highest in the first year of ART, and mycobacterial disease and CNS infections were the main causes of death.
in a study from Senegal. In South Africa, where *M. tuberculosis* and cryptococcal infections are common, IRIS is estimated to account for around a quarter of deaths and one-fifth of hospital admissions within the first six months of ART.

**Case Definitions**
One of the greatest obstacles to research on the epidemiology and pathogenesis of IRIS has been the lack of a widely accepted case definition or clear diagnostic criteria for IRIS. This is due to the difficulty of establishing generic criteria for a diverse range of clinical conditions and both paradoxical and unmasking IRIS, and limitations in laboratory facilities to support a diagnosis (e.g., histopathological evidence of an inflammatory response). IRIS remains a diagnosis of exclusion, after consideration of adverse drug reactions, new OIs, anticipated disease progression, and microbiologic treatment failure, whether due to drug resistance or malabsorption. Differentiation of IRIS from these other diagnoses has important management implications, and is also necessary for assessing the impact of IRIS on clinical outcome.

Two generic case definitions have been proposed and are summarized in Box 3. The first definition outlines two major and three minor criteria for IRIS, with the requirement of the first major criterion plus either the second major or at least two minor criteria to fulfill the diagnosis. A second definition, proposed by the AIDS Clinical Trials Group (ACTG), is based on three criteria, all of which must be met to diagnose IRIS. The ACTG definition was evaluated in a study in

---

**Box 3. Published Case Definitions for IRIS**

**Definition described by French et al**
Must meet both major A and major B criteria, or major A and any two minor criteria.

**Major Criteria A**
- Atypical presentation of opportunistic infections or tumors in patients responding to ART
- Localized disease (e.g., lymph nodes, liver, spleen)
- Exaggerated inflammatory reaction (e.g., severe fever, painful lesions)
- Atypical inflammatory response in affected tissues (e.g., granulomas, suppuration, necrosis, perivascular lymphocytic inflammatory cell infiltrate)
- Progression of organ dysfunction or enlargement of preexisting lesions after definite clinical improvement with pathogen-specific therapy before ART and exclusion of treatment toxicity and new diagnoses

**Major Criteria B**
- Decrease in VL greater than 1 log

**Minor Criteria**
- Increased CD4 T-cell count after ART
- Increase in an immune response specific to the relevant pathogen (e.g., delayed-type hypersensitivity response to mycobacterial antigens)
- Spontaneous resolution of disease without specific antimicrobial therapy or tumor chemotherapy with continuation of ART

**Definition cited by Robertson et al**
Must have all of the following:
- New onset or worsening symptoms of an infection or inflammatory condition following the initiation of ART
- Symptoms not explained by a newly acquired infection, the predicted course of a previously diagnosed infection, or the adverse effects of drug therapy
- Demonstration of a decrease of greater than or equal to 1 log in the number of HIV RNA copies
While the clinical features of IRIS are well documented, the immunopathogenesis (see Figure 2) remains poorly understood. IRIS is thought to be the consequence of restoration of an immune response against an opportunistic pathogen that is excessive and results in immunopathology detrimental to the host. As with the clinical presentation, the pathological and histological features of IRIS are diverse. The immunopathogenic mechanisms also appear to differ according to the type of pathogen. IRIS events associated with infections by intracellular pathogens, such as mycobacteria and fungi, are characterized by

**Figure 2. Summary of pathogenesis of and risk factors for infectious IRIS**

Reproduced with permission from Lippincott, Williams & Wilkins
and regulation of Treg cells in relation to IRIS remain poorly understood. A greater understanding of the immunopathogenesis is essential if prevention and treatment strategies are to be improved, particularly in resource-limited settings where rates of IRIS are high.

DIFFERENTIAL DIAGNOSIS AND INVESTIGATION OF SUSPECTED IRIS

In the absence of a diagnostic test or pathognomonic clinical features, the diagnosis of IRIS remains a process of exclusion. There are several possible explanations other than IRIS for a patient’s deterioration in clinical status after initiating ART (Box 4). The main differential diagnoses with possible paradoxical IRIS are suboptimal primary treatment of an OI (e.g., suboptimal antimicrobial therapy due to inappropriate drug selection or inadequate dosage, poor adherence, or reduced bioavailability resulting from malabsorption or drug interactions), resistance to the primary treatment regimen resulting in ART failure, natural history of underlying OI, newly acquired disease, and drug toxicity. The specific diagnostic workup will depend on the patient’s clinical presentation and the resources available.

Any patient presenting with symptoms suggesting a new OI or an HIV-related condition after ART initiation should be investigated for

---

**Box 4. Differential Diagnoses in Patients Experiencing Clinical Deterioration after Initiating ART**

- IRIS—paradoxical reaction (deterioration of known condition that would otherwise be expected to improve)
- IRIS—unmasking (new clinical presentation of undiagnosed but preexisting condition)
- Failure of OI treatment because of drug-resistant organism
- Failure of OI treatment because of nonadherence to OI treatment or prophylaxis
- Failure of ART because of drug resistance
- Failure of ART because of nonadherence to ART
- Failure of OI treatment or ART for other reasons (e.g., malabsorption)
- Newly acquired OI or other condition
- Expected course of preexisting OI or other condition
- Adverse drug reaction

granuloma formation, hypercalcemia, suppuration, and features of a delayed-type hypersensitivity reaction, and have been associated with increased production of interferon gamma (IFN-γ)–secreting antigen-specific T cells. A CD8 T-cell response appears to predominate in IRIS associated with some viral pathogens, such as herpes zoster, CMV, hepatitis C, or HHV-8. Common features of some types of IRIS are the production of proinflammatory cytokines (such as IFN-γ and interleukin [IL]-6) and lower concentrations of mediators (such as IL-10 and IL-2), polymorphisms of cytokine genes and major histocompatibility complex (MHC) haplotypes have been identified as genetic markers of increased risk of IRIS.

It has also been proposed that IRIS may result from an imbalance of pathogen-specific effector and regulatory cellular immune responses shortly after initiation of ART. In particular, defective functioning of regulatory T cells (Tregs), the centrally important T cells in the regulation of cellular immune responses, may contribute to the immunopathogenesis of IRIS. For example, with TB IRIS, a slow reconstitution of *M. tuberculosis*–specific Treg cells as compared to the corresponding T effector cells may lead to the loss of control of inflammatory CD4 T-cell responses against active TB and lead to “paradoxical” TB-IRIS. However, the processes involved in the induction
treatment failure due to either nonadherence or drug resistance to both ART and other antimicrobial therapy. ART failure may be defined using clinical, immunological, or virological criteria and is covered in detail in the chapter entitled “Antiretroviral Treatment Failure, Drug Resistance, and Management of Therapy-Experienced Patients.” Although virological criteria provide the most objective assessment of treatment failure, VL assays are unavailable in many clinical settings, and so immunological criteria based on the absolute CD4 count are often used. However, this may be of limited value in discriminating between treatment failure and IRIS, as the latter can emerge in the absence of a good CD4 response. Overall, a rising CD4 count is more useful in supporting a diagnosis of IRIS than a falling CD4 count is in excluding it.

Exclusion of a clinical presentation consistent with the predicted course of a known OI as a differential diagnosis is problematic because some OIs (e.g., cryptococcal meningitis, progressive multifocal leukoencephalopathy [PML]) can deteriorate in patients despite appropriate antimicrobial therapy, as a result of overwhelming infection or poor immune status. In addition, conditions such as chronic diarrhea and eosinophilic folliculitis may undergo a relapsing/remitting course despite ongoing therapy.

The differential diagnosis of unmasking IRIS mainly includes newly acquired OIs and the emergence of latent infections due to immunosuppression. When dealing with infections that are endemic in the population, making that distinction can be challenging, even when sophisticated imaging or histology is available. A detailed clinical history and examination performed before starting ART may often identify minor or moderate symptoms that can be attributed retrospectively to a subclinical process that was unmasked by ART.

A temporal relationship with the initiation of ART is the most consistent feature of IRIS. Of 11 studies reporting the median time between the start of ART and the onset of IRIS, 9 studies reported an interval of less than three months. The two outlying estimates are 20 weeks and 34 weeks, the latter being in a cohort of patients with cryptococcal disease. It may be that some OIs, such as cryptococcosis, have long latencies before IRIS onset, whereas others, such as TB, occur much earlier (e.g., after a median of 2 weeks in two studies). As a general rule, IRIS should be considered as a possible diagnosis whenever a clinical problem presents less than three months after commencement of ART.

**PREVENTION OF IRIS**

At present, there are no evidence-based guidelines to treat or prevent IRIS. Given present knowledge, some recommendations to prevent IRIS can be made. A low CD4 count has been identified as a risk factor for IRIS in a range of clinical settings; therefore, initiation of ART at an earlier stage of disease would be associated with a lower rate of IRIS. This clearly presents challenges in resource-limited settings, where patients are often diagnosed with HIV and initiate ART at a late stage of disease.

A short duration of OI therapy at the start of ART has been identified as a further risk factor for IRIS in several studies. Therefore, delaying ART until at least two months of OI therapy have been completed would lower the pathogen burden and reduce the risk of IRIS. However, the potential benefits of delaying ART to prevent IRIS in patients receiving treatment for an OI need to be weighed against the risk of developing other OIs if ART is delayed. A recent trial in patients with non-TB OIs showed decreased rates of AIDS progression and death in patients initiating ART at a median of 12 days after initiation of OI therapy versus 45 days (14% vs. 24%, respectively) with
and life-threatening disease requiring temporary interruptions of ART and use of aggressive anti-inflammatory therapy. Because of the wide and varied clinical spectrum of IRIS, it is impossible to list all the possible scenarios and management steps required. Table 3 and Figure 3 provide a broad summary of the key considerations in the evaluation and management of IRIS.

**Decision to Continue ART**

Illnesses occurring early after initiating ART may have an impact on adherence. It is therefore important that patients are informed in advance about potential IRIS and advised that this is part of the process of immune recovery and not a reason to discontinue ART. ART will usually only need to be discontinued in exceptional circumstances of serious, life-threatening IRIS events. For patients with hepatitis, uncertainty may surround the relative contributions of drug toxicity and IRIS to the condition, because abnormal liver function tests may result directly from ART toxicity. Furthermore, patients with mycobacterial infections may present with liver enzyme abnormalities suggestive of hepatic infiltration caused by either disease progression or IRIS while taking hepatotoxic antimycobacterial drugs.

In cases of cutaneous eruptions, it is usually possible to distinguish the appearance of typical

**Table 3. Clinical Management of IRIS**
Specific treatment of the OI or Inflammatory Condition

Antimicrobial therapy will depend on the nature of the causative pathogen and whether it is a paradoxical or unmasking event. Treatable OIs that may be unmasked by IRIS include mycobacterial diseases and fungal and parasitic infections. Although their presentations may be atypical, the treatments for these infections should follow standard local management. If IRIS is the most likely diagnosis, and OI therapy is already optimal, and the associated clinical manifestations are serious, consideration...
should be given to the use of corticosteroids or other immunomodulatory therapy (discussed in the next section). In cases of space-occupying lesions in the CNS (e.g., cryptococcomas or tuberculomas), raised ICP with a reduced level of consciousness or other neurological deficit, respiratory failure, lesions close to major airways, or other critical situations, it is wise to intensify antimicrobial treatment and add an immunosuppressant agent such as dexamethasone. Cryptococcal meningitis IRIS should not require intensification of antifungal therapy unless cryptococcal treatment failure is suggested by persistently positive CSF fungal cultures or India ink staining. Paradoxical cryptococcal peripheral lymphadenitis may be managed conservatively unless fluconazole resistance is suspected. Most cases reported in the literature have been managed by an increase in fluconazole dosage, although no evidence supports the practice.

OIs that result in latent or persistent infections, such as HSV, human papillomavirus, hepatitis B and C, and VZV, may present as IRIS. Genital HSV is often clinically indistinguishable from other ulcerating sexually transmitted infections (STIs), such as syphilis, chancroid, or lymphogranuloma venereum. Local antibiotic protocols for STIs should be used to manage these conditions. Both unmasking and paradoxical IRIS may be self-limiting and thus amenable to conservative management in less severe cases.

Inflammatory dermatoses, such as papular pruritic eruption and eosinophilic folliculitis, are often associated with IRIS. Treatment typically consists of mild to moderate topical steroids and an oral antihistamine. Treatment is usually continued for one to two months until the condition resolves. If an initial response to therapy does not occur and the dermatosis is disfiguring or disabling, dermatological advice should be sought.

**Role of Immune-Modulating Drugs**

Few data are available from randomized controlled trials on the use of corticosteroids or other immunomodulatory drugs in the treatment of IRIS. There are, however, several case reports of good response to different treatments, including non-steroidal anti-inflammatory drugs (NSAIDs) for cryptococcal lymphadenitis, thalidomide for TB and cryptococcal IRIS, montelukast for leukocytoclastic vasculitis and urticaria, and infliximab for a paradoxical reaction to CNS TB in an HIV-negative patient. High doses of corticosteroids (prednisone 0.5 to 1.5 mg/kg daily) have been used in a range of settings. In patients on ATT, an important pharmacokinetic interaction between rifampin and prednisone requires an increase in the dose of prednisone. The use of corticosteroids to suppress an immunopathological response as treatment for mild to moderate TB IRIS has also been examined in a randomized controlled trial. This South African study of 109 subjects found a significant reduction in the number of hospital days among patients treated with four weeks of high-dose prednisone compared to placebo (282 vs. 463 days of hospitalization and 29 vs. 38 procedures, respectively) with no overall difference in deaths or adverse drug reactions.
Box 5. Key Points

Chapter Key Points Summary

- IRIS occurs in 10%–40% of patients, usually within three months of starting ART.
- IRIS may occur in response to a wide range of infections and other diseases.
- There are two main scenarios of IRIS: paradoxical deterioration and unmasking of an undiagnosed condition.
- The epidemiology of IRIS in resource-limited settings is not well described.
- Risk factors for IRIS include advanced immunosuppression and short duration of treatment for an OI before initiation of ART.
- Alternative diagnoses include treatment failure, new infections, adverse drug effects, and expected course of a known condition.
- ART should be continued in most cases of IRIS.
- OI treatment may need to be intensified in some situations.
- Corticosteroids or other anti-inflammatory drugs are often used in severe or serious cases of IRIS; however, the evidence in support of their use is weak.
- IRIS may be prevented or anticipated by careful assessment before initiating ART and a good understanding of the risk factors.

associated with unmasking and paradoxical presentations of TB IRIS. Paper presented at: 16th Conference on Retroviruses and Opportunistic Infections; February 8-11, 2009; Montreal, QC, Canada. Abstract 773.

INJECTION DRUG USE AND THE RELATED practices of sharing injection equipment are a major driver of the HIV epidemic in many parts of the world. One-third of new HIV infections outside sub-Saharan Africa are related to injection drug use. In the explosive epidemics seen in such regions as Eastern Europe and Central Asia, more than 80% of HIV cases are related to injection drug use.\textsuperscript{1,2} Injection drug use is also emerging as a public health concern in areas of Africa, particularly Kenya, Tanzania, South Africa, Nigeria, and Mauritius.\textsuperscript{3} In 2005, 90% of new HIV cases in Mauritius were related to injection drug use, up from 7% of cases in 2001.\textsuperscript{3} HIV prevalence among injection drug users in Mombasa, Kenya, and South Africa has been reported as 31% and 28%, respectively.\textsuperscript{1,3}

Sexual transmission from injecting drug users living with HIV to their sex partners is an important secondary route of spread, extending to perinatal transmission of HIV. Injecting drug users are often the conduit through which the virus moves from high-risk populations into the general population. Women who are not participating in any high-risk behaviors are often infected with an HIV-positive partner with a remote or recent history of injection drug use (while in a monogamous relationship). Injecting drug users who are incarcerated may also acquire HIV infection through sexual contact in prison, with subsequent exposure of their spouses, sexual partners, and children upon release. From a public health perspective, an important rationale for treating injecting drug users and keeping them in care is the role that high-risk behaviors play in the spread of HIV infection into the general population. Programs that reach out and engage injecting drug users and assist them in commencing drug or substitution therapy treatment can help reduce high-risk behaviors through better access to social services (housing, food). Such programs can also provide HIV-related services to this highly vulnerable population, which in turn can have a significant impact on limiting the growth of the HIV epidemic.

Injection drug use presents many challenges to the HIV health-care provider. Injecting drug users are often burdened by issues of adherence, addictive behavior, mental illness (depression more commonly than psychosis), and coinfection with hepatitis B, hepatitis C, and TB, along with recurrent bacterial infections. Limited availability of effective drug treatment in many resource-limited settings, and restrictive policy environments marked by harassment and social stigma, contribute to the
marginalization of injecting drug users and foster the silent expansion of the HIV epidemic. The complexity of these social, medical, and treatment issues often makes the injecting drug user difficult to identify and enter into and retain in care. For these reasons, targeted strategies are needed that foster unique alliances between medical treatment services, social services, drug treatment professionals, law enforcement, and civil society in order to create and sustain an effective interface with injecting drug users and address their HIV prevention and treatment needs over the course of disease.

There is abundant evidence that injecting drug users can be engaged and retained in medical treatment for HIV and that treatment outcomes on antiretroviral therapy (ART) are often equivalent to or better than those of non-injection-drug-using patients. Integrated approaches that involve knowledgeable medical providers, peer education and support, community services, and drug treatment (e.g., concurrent opioid substitution therapy), as well as various models of directly observed therapy, have all been shown to increase the adherence and retention of injecting drug users in care.

This chapter will address the issues that affect access to effective HIV treatment among injecting drug users, followed by a review of the medical management of HIV-positive injecting drug users, including the provision of ART. A summary of prevention strategies and the role of the medical provider in developing continua of prevention and treatment is also provided.

ACCESS TO HIV TREATMENT

Suboptimal access to effective ART and opportunistic infection prophylaxis by HIV-positive injecting drug users has been documented in numerous studies. Among the factors contributing to this lack of access are the negative attitudes of some medical providers toward injecting drug users and perceptions that they are unable to adhere to medication regimens. In a recent national survey of HIV-positive patients and their physicians (in the United States), 23% of patients were receiving care from physicians who harbored negative attitudes toward injecting drug users, reflected by their agreement with statements such as “treating injecting drug users seems futile” and “when given a choice, I would not treat injecting drug users with HIV infection.” Medical providers may hold the beliefs, commonly found in society at large, that drug users have brought their illness upon themselves, that drug users don’t care about their health, and that the injecting drug user is essentially a different type of person from the rest of the population. Allowing generalized thinking or biases toward a group to influence therapeutic decision making for an individual is fraught with ethical problems.

These personal biases are often compounded by a lack of professional training in substance abuse disorders, which can lead to misunderstanding and frustration on the part of physicians when dealing with the physiological and psychological aspects typical of chronic addiction. Many physicians fail to understand the chronic and relapsing nature of substance abuse and lack appreciation of substance abuse as a biological and medical disease that is compounded by a high rate of coexisting mental illness. Drug treatment strategies and the nature of addiction are generally not part of traditional medical training, and a climate of mutual distrust between providers and patients is common. For instance, patients may feel they are being intentionally mistreated or punished for their addiction by their provider. That perception must be modified by providing appropriate training to increase provider competence and confidence in working with injecting drug users, aided by a thorough understanding of the natural history of addiction that helps them to form realistic expectations for these patients.

It is imperative that health professionals realize the role an overtly judgmental attitude plays in
preventing injecting drug users from being engaged and retained in care. It is not the role of the provider to judge someone’s behavior, as civil society assumes this function. The attitude of medical providers related to drug abuse is critical to the development of a trusting relationship with their patients (see Box 1). Clinicians who openly diminish the needs, complaints, or requests of patients with addiction are frequently excluded from decisions that influence a patient’s ability to maintain adherence to or enter into long-term care. The injecting drug user must feel embraced and respected in the treatment setting, and it is the responsibility of the provider to make sure that occurs.

The ability of injecting drug users to access prevention services and medical treatment for HIV is also frequently limited by other structural factors, such as discrimination, poverty, and criminalization of drug-related behavior. When given equal access to care, injecting drug users are less likely to have undetectable viral loads; however, when adherence factors are adjusted for, injecting drug users and non–drug users who achieve viral suppression have similar rates of viral load suppression and rebound, suggesting that other barriers exist to successful treatment that must be taken into account when planning services. The presence of comorbidities such as mental illness and polysubstance use (including alcohol abuse) can affect housing stability, food security, and personal safety, resulting in immediate needs that may overshadow health-seeking behaviors or engagement in care. However, the data are clear that injecting drug users can effectively follow ART regimens and remain in care and treatment, with the same or better outcomes than people without a history of injection drug use.

Active drug use itself does not decrease the effectiveness of ART. Rather, among active users, the success or failure of treatment correlates to the degree to which active drug use results in disruption of the patient’s daily activities. Injecting drug users in supportive treatment environments have been shown to have comparable adherence rates, drops in viral load, and increases in CD4 lymphocyte counts as non-injecting drug users. When injecting drug users are successful in achieving durable undetectable viral loads, they experience the same positive clinical outcomes as non-injecting drug users. It is important to note that providers should not withhold ART or require ongoing treatment for substance abuse as a prerequisite for starting ART. When additional comorbidities, such as alcohol abuse and/or psychiatric illness, are present, special strategies need to be developed to identify, enter, and retain the patient in a continuum of medical care. That continuum can facilitate access to medical treatment, psychiatric care, social services, and harm-reduction strategies throughout the course of the patient’s illness.

Different models exist for delivery of primary care to HIV-positive injecting drug users. Medical care combined with psychiatric services, social

---

Box 1. Principles to Enhance Patient-Provider Interaction

Providers should discuss the following key points with their patients regarding HIV and addiction:
- Physical/psychological effects of continued drug use
- Impact of drug use on the spread of HIV
- Benefits to the patient from both drug treatment and HIV treatment
- Impact of drug use on adherence

To foster a climate of mutual respect, the patient and provider should do the following:
- Agree on the respective roles of the patient and provider
- Set appropriate limits and, if needed, establish a patient-provider contract (e.g., “patient agrees to be truthful about concomitant drug use”)
services, and harm-reduction interventions are the core services needed, along with case management. Patients are often followed up with at a primary care clinic by case managers and/or counselors. Primary medical care can be provided on-site at drug treatment programs, or a substance abuse treatment component can be brought into an HIV primary care clinic. Integration of HIV treatment within opioid substitution therapy programs (i.e., methadone, buprenorphine) has also been implemented in some settings. Other approaches, such as directly administered antiretroviral therapy and modified directly observed therapy (MDOT) (i.e., three to five days of directly observed therapy [DOT], then self-administered two to three days per week), have been used to increase adherence and successful treatment outcomes among injecting drug users and others with substance abuse issues. However, both DOT and MDOT should be reserved for those who are not optimally adherent to ART, as such strategies are generally not needed for all injecting drug users. The role of peer educators and/or community support should be emphasized as well; HIV-positive injecting drug users on ART can be very effective in helping other patients live with their disease and manage their medications effectively.

**MEDICAL MANAGEMENT OF HIV INFECTION IN INJECTING DRUG USERS**

**Natural History of HIV Infection**

Most epidemiological data have found no difference in HIV progression between injecting drug users and non-injecting drug users in the pre-ART era. A study of 639 women over a seven-year period identified no difference in progression to AIDS between women who had past, current, or no history of injection drug use. Some in vitro and laboratory-based studies suggest that cocaine, methamphetamine, and heroin promote HIV replication, but the relevance of this to clinical outcomes has not been demonstrated. Two studies of a large urban cohort post-ART found that self-reported heroin and cocaine use were temporally associated with the development of new AIDS-defining conditions. The observation of more rapid HIV disease progression among injecting drug users relative to other risk groups may be related to the higher prevalence of comorbidities such as hepatitis B and C, late initiation of ART, or poor adherence. Early case identification combined with harm-reduction measures, drug treatment, and treatment of coinfections holds the potential to change this trajectory.

A prevention opportunity exists in the active using population of injecting drug users. A needle exchange strategy for HIV-negative active injecting drug users can reduce HIV transmission as well as transmission of hepatitis C virus (HCV) and hepatitis B virus (HBV). In addition, targeting HIV-negative active injecting drug users for early detection of primary infection provides an opportunity to prevent transmission before newly infected individuals seroconvert.

**Approach to the Patient**

Substance abuse often goes unrecognized by clinicians unless a careful history is taken along with a physical exam. The presence of a substance abuse diagnosis may reveal multiple comorbidities that bear on both diagnostic and care decisions. Medical systems are prejudicial toward the active injecting drug user, and the social and legal implications of a diagnosis of active substance abuse for the patient must be acknowledged. It is important to take the time to understand the unique characteristics of the injecting community and the social system of the injecting drug user, both to better inform medical care and to take advantage of the opportunity to promote prevention measures that can reduce health risks for sexual and injection-equipment-sharing partners.
Providing HIV care for active injecting drug users presents unique and sometimes overwhelming challenges. Many of the HIV epidemics in Russia, Ukraine, Vietnam, and some communities in Thailand have been driven by injection drug use. Providing HIV care is made all the more difficult by the stigmatization and criminalization of substance use in these settings. In many parts of the world, active substance use is not seen within the context of a medical condition, but rather within the context of criminal behavior that warrants punishment. This unfortunate reality makes providing HIV care to substance users all the more difficult and, paradoxically, can also make providing effective treatment for substance abuse more difficult.

First and foremost, individuals engaging in substance use need to be enrolled in a care program that emphasizes trust and builds a relationship with the patient based on compassionate care. This will lead to an open exchange of information in which the care provider can address the multiple ongoing issues facing substance users, including the need for substance abuse treatment, safer injection practices, and violence avoidance, as well as medical treatment for TB, bacterial infections, and HIV/AIDS. Care providers can begin to address the complex social challenges facing injecting drug users only after they have established trust and rapport with their patients.

Most injecting drug users who enter into care will be symptomatic with bacterial skin infections, pneumonia, active TB, or opportunistic infections. The priority is to treat the opportunistic infections and then to begin ART as soon as possible. TB may be the most common opportunistic infection in HIV-positive injecting drug users. The presence of TB infection will require diagnostic studies and initiation of anti-TB therapy that utilizes four drugs for patients with active disease.

Injecting drug users presenting with bacterial infections, TB, skin infections, or frank opportunistic infections should routinely be offered HIV testing. HIV testing should be offered frequently and routinely both for symptomatic and asymptomatic injecting drug users. Each HIV test represents an opportunity to reinforce risk-reduction messages as well as to inform both the individual patient and, through the patient, the substance-using community that effective treatment for HIV infection is available.

Although the challenges of providing HIV care for substance users are formidable, the rewards can be great. Many people with active substance use have never been treated with care, compassion, and respect. The provision of compassionate HIV care can serve as an impetus for such people to enter substance abuse treatment and turn around their lives. In this way, HIV treatment can be a transforming event that is highly rewarding for both the patient and care provider.
Empathy and a nonjudgmental approach are critical in obtaining a comprehensive and accurate history of substance abuse, including alcohol, illicit/recreational drugs, and prescription opiates and benzodiazepines. Understanding that addiction may involve multiple substances can make taking a history more complex. Medical schools often do not emphasize the complex medical and psychosocial aspects of treating the active injecting drug user who is HIV infected. The use of stimulants (i.e., sympathomimetics) and alcohol are associated with increased sexual activity, which can place the injecting drug user at an even greater risk of acquisition and transmission of HIV.

**History Taking and Physical Examination**

The key points to look for when taking the history of an injecting drug user are summarized in Box 2. Common findings to look for during the physical examination that will provide information about recent substance use, withdrawal status, and intoxication are provided in Box 3. Complications related to end organ damage to the heart, kidney, liver, and lungs may also be identified.

There are a number of physical findings seen in HIV-positive injecting drug users that can be due to HIV infection, HIV-related opportunistic infection, or substance abuse (see Table 1). Since the etiology of these findings can be difficult to differentiate, a careful history and physical examination, as well as clinical monitoring, may be required to arrive at an accurate determination of the cause.

**Bacterial Infection of the Skin and Heart Valves**

Bacterial infections, including pneumonia, endocarditis, and sepsis, are common among both HIV-positive and HIV-negative injecting drug users. Pneumonia is four times more common in HIV-positive injecting drug users than in those who are HIV-negative, with *Pneumococcus* and *Haemophilis influenzae* being the most common pathogens. There is an increased incidence of Gram-negative pneumonia among active injecting drug users, especially with concomitant alcohol use. Due to the potential for an altered mental status causing somnolence, opiate-addicted patients have a higher incidence of aspiration pneumonia with mixed aerobic and anaerobic infections. It is important to remember that the majority of patients respond well to appropriate antibiotic treatment guided by culture and sensitivity tests.

Generalized lymphadenopathy was a common clinical manifestation of HIV disease in the pre-ART era, and swelling of four or more lymph node groups is still a common clinical presentation of AIDS. Injecting drug users often have swollen lymph nodes as a result of chronic and recurrent antigenic stimulation of the regional lymph nodes (i.e., epitrochlear and axillary) that drain the most frequently used injection sites. Bacterial infection (lymphadenitis and subcutaneous abscess) must be ruled out in such cases.

During physical examination, the common manifestations of acute and subacute bacterial endocarditis should be looked for. Those include both immunological (e.g., Janeway lesions on the fingers or toes, Roth’s spots) and embolic phenomena (e.g., Osler’s nodes, splinters in the nail bed, hematuria, amaurosis fugax, etc.). Signs of hypotension, vasodilatation, and diminished renal output may be reflective of congestive heart failure due to a variety of causes (e.g., valvular heart disease).

**HIV and TB Coinfection**

The association of HIV and TB in the injecting drug user population has been well established worldwide. Before the emergence of the HIV epidemic, injection drug use was recognized as an independent risk factor for TB; low socioeconomic status, homelessness, poor nutrition, overcrowding,
of continuous anti-TB therapy. As with ART, the approach to TB treatment should be informed by the patient-provider partnership and tailored to the circumstances of the individual patient. In some cases, variations on the DOT model may be needed for patients having difficulty with adherence. It is generally recommended that treatment of active TB be continued for two months before initiation of ART, to avoid precipitating immune reconstitution inflammatory syndrome.23

Drug interactions associated with HIV-TB cotreatment include the potential interaction of rifamycin-based medications with both protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). These interactions can result in subtherapeutic serum drug levels of various antiretroviral drugs (ARVs) (e.g., nevirapine, PIs, maraviroc, raltegravir). Further information on potential drug interactions can be found elsewhere in this volume.

Source: O’Connor et al.17

HIV-positive injecting drug users are at a much higher risk for TB infection, and for progression from latent infection to active TB, compared with HIV-negative injecting drug users and the general population.28 Although TB is predominately a pulmonary infection, up to 40% of HIV-positive patients may develop extrapulmonary disease.28 A full discussion of the diagnosis and treatment of HIV-TB coinfection is provided elsewhere in this volume. Adherence to TB medications for the full course of therapy is the most important factor in determining treatment outcomes, with excellent results expected within six to nine months of continuous anti-TB therapy. As with ART, the approach to TB treatment should be informed by the patient-provider partnership and tailored to the circumstances of the individual patient. In some cases, variations on the DOT model may be needed for patients having difficulty with adherence. It is generally recommended that treatment of active TB be continued for two months before initiation of ART, to avoid precipitating immune reconstitution inflammatory syndrome.33

Drug interactions associated with HIV-TB cotreatment include the potential interaction of rifamycin-based medications with both protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). These interactions can result in subtherapeutic serum drug levels of various antiretroviral drugs (ARVs) (e.g., nevirapine, PIs, maraviroc, raltegravir). Further information on potential drug interactions can be found elsewhere in this volume.
The choice of ARV regimens should be informed by the HBV and HCV status of HIV-positive injecting drug user patients. For patients ready to start ART, the antiviral effect of lamivudine and tenofovir is beneficial due to the anti-HBV activity of these drugs. Providers should be aware that the discontinuation or switching of these drugs can trigger a reactivation or flare of acute HBV.

Underlying hepatic disease in injecting drug users also complicates the diagnosis of liver function abnormalities that can result from toxicity to ART regimens and other commonly used medicines in HIV care (e.g., trimethoprim-sulfamethoxazole, rifampin, pentamidine, dapsone, isoniazid, pyrazinamide, etc.). Chronic HCV infection is associated with an increased risk of drug-induced hepatotoxicity, requiring closer monitoring of serum transaminases and patient symptoms until patients are stable on a specific ART regimen.

**HIV and Hepatitis Coinfection**

Injecting drug users are at high risk for all forms of infectious hepatitis and alcoholic hepatitis. HCV/HBV and HIV are all most efficiently spread through direct exposure to contaminated blood, which may remain on used needles or injection equipment. Incidence of HIV and HCV coinfection varies depending on individual risk behaviors, but prevalence rates of 70% to 80% have been reported among injecting drug users. Liver disease due to chronic HBV and HCV infection is becoming a leading cause of death among HIV-positive individuals worldwide, highlighting the need to pursue prevention strategies, including the supplying of single-use or sterilized injection equipment and, for those with a CD4 lymphocyte count of greater than 200 cells/mm³ (i.e., those able to mount a protective immune response), provision of hepatitis B vaccine.
infection on the rate of HIV disease progression are less clear cut, with conflicting study findings.31,33 The standard of care for HCV-HIV coinfected patients is pegylated interferon alfa plus ribavirin. All patients should be counseled to eliminate alcohol intake and acetaminophen use, and the emphasis should be on selecting an ART regimen with a lower hepatotoxicity profile and ramping up support for adherence.

### Hepatitis C Coinfection

The natural history of HCV infection is accelerated in patients living with HIV, with an increased rate of progression to cirrhosis, end-stage liver disease, hepatocellular carcinoma, and death.31 Combination ART that results in restored immune function has been shown to decrease the rate of death due to HCV liver disease.32 However, the effects of HCV infection on the rate of HIV disease progression are less clear cut, with conflicting study findings.31,33 The standard of care for HCV-HIV coinfected patients is pegylated interferon alfa plus ribavirin. All patients should be counseled to eliminate alcohol intake and acetaminophen use, and the emphasis should be on selecting an ART regimen with a lower hepatotoxicity profile and ramping up support for adherence.

Hepatitis B Coinfection
HBV infection in HIV-positive persons increases the risk of cirrhosis, end-stage liver disease, and death, particularly in patients with a low CD4 lymphocyte count or alcohol use. Injecting drug users may contract HBV through blood-borne exposure from injection practices, or through sexual transmission. The prevalence of HBV-HIV coinfection is lower than that of HCV-HIV coinfection in the United States (5% to 10%) and Asia (20% to 30%), but may be higher within smaller communities of injecting drug users.\textsuperscript{30,31} Chronic HBV infection develops in 20% of HIV-positive adults following HBV exposure.\textsuperscript{31} HIV-positive patients should be vaccinated against both HBV and hepatitis A, due to the increased severity of hepatitis in patients with preexisting liver disease. For all nonvaccinated injecting drug users, vaccination is a critical primary care intervention before immune damage becomes severe. A more detailed discussion of HBV-HIV coinfection is provided elsewhere in this volume.

Sexually Transmitted Infections
Sexually transmitted infections (STIs) have long been associated with substance abuse, both due to the frequent exchange of sex for money and the sexual disinhibition that results from sympathomimetics (e.g., cocaine) and alcohol alone or in combination. Cocaine, crack, and alcohol use have been linked to an increased risk of syphilis and other ulcerative genital infections.\textsuperscript{34,35} Medical providers should remain alert to the risk of STIs in patients who may be engaging in transactional sex for drugs. There is also a high risk of cervical dysplasia and cancer associated with human papillomavirus. High false-positive rates of rapid plasma reagin in injecting drug users favor the use of the fluorescent treponemal antibody-absorption test to screen for syphilis in this population. HIV-positive injecting drug users with genital herpes may require longer therapy and suppressive dosing for symptom recurrence; fungal infections also require longer initial therapy, with continued suppression often needed due to the frequent recurrence of symptoms.

Cancer
There are reports that injecting drug users experience a more aggressive clinical course for cancer compared with non-injecting drug users at the same stage of disease. Cancer of the lung is seen in injecting drug users as young as 30 to 40 years of age and is particularly aggressive.\textsuperscript{36,37} Lack of recognition of Kaposi’s sarcoma by physicians who are not primed to recognize this condition may explain the low reported incidence of Kaposi’s sarcoma in injecting drug users; for instance, multiple skin lesions resulting from injection practices can complicate the detection of developing Kaposi’s sarcoma. At present, there are no data on the prevalence or outcomes of lymphoma in injecting drug users.

Psychiatric Illness and Cognitive Dysfunction
In developed countries, there is a significant coexistence of psychiatric disorders among HIV-positive injecting drug users, with disorders in this group occurring at a rate roughly 6% higher than in the general population. Among those with active addictions to opioids, the lifetime rate of major depression is greater than 53%, compared with greater than 40% among cocaine users, and greater than 35% among heavy alcohol users. Other affective disorders include antisocial personality disorders and anxiety. Providers working with injecting drug users must actively screen for suicidal tendencies among their patients, as well as be ready to intervene with multidisciplinary treatment plans when paranoia and psychosis are identified. These disorders can be difficult to differentiate from organic syndromes directly related to HIV infection or chronic secondary infections and malignancies. A higher index of suspicion should be maintained.
are consistent with the revised U.S. Department of Health and Human Services ARV guidelines, which recommend maximizing the preservation of immune function in HIV-positive individuals.23

Considerations guiding the selection of ARV regimens for injecting drug users include (1) presence of HBV and/or HCV coinfection; (2) side-effect profiles; (3) preexisting psychiatric illness (if efavirenz is being considered); (4) drug interactions, including ARV-methadone interactions; and (5) complexity of the regimen in terms of pill burden and dosing frequency. The benefit of lamivudine and tenofovir for patients with HBV-HIV coinfection has been previously discussed. Switching an HBV-positive patient off a regimen containing lamivudine or tenofovir can trigger a moderate to severe reactivation of HBV disease due to a rebound of HBV viral loads.

Due to the higher incidence of hepatic, renal, gastrointestinal, and hematologic diseases in injecting drug users, they are more likely to experience ARV-related side effects and toxicities. Baseline assessment of HBV and HCV status is required, along with serum transaminases at baseline and at frequent intervals during the first three months of therapy in HBV-positive or HCV-positive patients. Although nevirapine can be used safely in these patients with close monitoring, less hepatotoxic agents may be preferred where available. Use of nevirapine should, however, be avoided in women with baseline CD4 counts greater than 250 cells/mm³ and in men with baseline CD4 counts greater than 450 cells/mm³. Impaired renal function in patients with a history of glomerulonephritis would indicate caution in the use of tenofovir or indinavir.23 A common side effect when starting efavirenz is vivid nightmares for the first month of treatment, along with less frequently reported dizziness, hallucinations, and mood changes.23 More severe mental illness, including rapid development of psychosis, has rarely been reported. Clinicians...
should exercise caution when considering the use of efavirenz in persons with any history of mental illness, and patients need to be educated about possible symptoms and instructed to report them to their providers if they should develop.

Special attention should be given to the effect of methadone on ARVs, and vice versa. Among the nucleoside reverse transcriptase inhibitors (NRTIs), none have a clinically significant effect on methadone metabolism. Conversely, methadone has been shown to increase the area under the curve (AUC) of zidovudine by 43%, and providers should be alert to potential zidovudine toxicities (e.g., bone marrow suppression). A 27% decrease in stavudine blood levels is reported with methadone but no dose adjustments are needed. There are no clinically significant interactions of methadone with abacavir or tenofovir.

The NNRTIs are potent inducers of the p450 cytochrome system, which decreases methadone blood levels. Nevirapine has been reported to reduce methadone AUC by 46% and efavirenz has been reported to reduce methadone AUC by 50%-60%, commonly inducing opiate withdrawal symptoms within seven days of treatment initiation. Delavirdine inhibits the p450 cytochrome system and increases methadone AUC by 19%, but this rarely requires a dose adjustment.

Efavirenz and nevirapine decrease methadone levels by 43% and 46%, respectively, and often induce opiate withdrawal symptoms within seven days of treatment initiation. Such occurrences should be dealt with by increasing the methadone dose by 5 to 10 mg/day or until the patient no longer experiences withdrawal symptoms. Delavirdine inhibits the p450 cytochrome system and increases methadone levels, but this interaction rarely requires a dose adjustment.

PIs are generally not affected by methadone, with the exception of amprenavir. Amprenavir is reduced by 30% when taken with methadone, but the dose rarely needs to be increased. Nelfinavir, lopinavir/ritonavir, saquinavir, ritonavir, and amprenavir all reduce methadone AUC, but a clinically significant need for dose adjustments has not been shown. Buprenorphine is also widely used in drug substitution therapies for opiate addiction. It has not been shown to have any interactions with ARVs, or vice versa.

A summary of the data on methadone-ART interactions for ARVs is provided in Table 2. The AUC measures the blood level of a drug over a period of time.

The complexity of ART regimens in terms of pill burden and frequency of dosing is inversely related to successful adherence. The increased availability of effective fixed-dose combinations may offer significant benefits to injecting drug users in terms of simplifying the process of taking ARVs.

In addition to those routinely discussed, it is important to mention some additional barriers to adherence for injecting drug users. For active injecting drug users, addiction is a competing priority that overshadows their daily activities and motivations. The ability to develop routines or follow a time schedule for medications linked with a regular activity may be difficult, particularly for people without stable housing. Arrest or incarceration may also interrupt treatment. Yet one of the greatest barriers to successful treatment in this population is mistrust between the medical provider and the drug user, limiting the ability to discuss the patient’s injection drug use, the realities of his or her life and competing priorities, and potential strategies that can improve adherence. One of the most powerful factors supporting a patient’s adherence to ARV regimens is the health provider’s attitude toward the patient. When patients believe that a medical professional is truly working in their best interests and mutual respect exists between patient and health professional, it serves as a strong motivation for patients to follow recommended treatment.
HIV PREVENTION
The explosion of HIV/AIDS within populations engaging in injection drug use requires immediate action. A two-pronged approach is needed that both reduces the burden of drug addiction through prevention and drug treatment and reduces the health consequences of ongoing drug use for injecting drug users, their partners, and needle-sharing networks. The current situation is critical: the Joint United Nations Program on HIV/AIDS (UNAIDS) estimates that only 8% of injecting drug users worldwide have access to HIV prevention services, although 80% coverage is required to effectively slow the epidemic.1

The sharing of contaminated injection equipment has become the primary mode of HIV transmission in many countries throughout Eastern Europe, the Commonwealth of Independent States (made up of 11 former Soviet republics), and significant regions in Asia.1 Needle and syringe exchange (NSE) programs have had documented effectiveness in reducing the sharing of used needles and syringes, as well as in reducing unsafe injection and disposal practices; NSE programs have also been associated with decreased frequency in injection practices.48 NSE programs typically include other prevention interventions such as counseling, education, condom distribution, and referrals to drug treatment and health care. For individuals who are actively injecting drugs, information coupled with the availability of sterile equipment can be a lifeline to reduce the risks of blood-borne transmission of HIV and hepatitis. Active users should also be educated about sterile injection techniques and the early recognition and care of abscesses. In recent years, naloxone has been introduced for use as a lifesaving intervention in the setting of a witnessed overdose. The use of predrawn syringes filled with naloxone, along with accompanying education, has been considered in some cities in the United States to reduce the number of deaths resulting from drug overdoses. Medical providers should become familiar with the availability of these risk-reduction services for their patients who are active drug users, regardless of HIV status.

There is strong and consistent evidence that opioid substitution treatment is effective in reducing use of opioids and increasing the retention of opioid-dependent individuals in drug abuse treatment and medical services.48 Methadone maintenance treatment reduces drug-related HIV risk behavior, including frequency of injections and sharing of equipment. Several studies have also shown a reduction in sex-related HIV risks among participants in methadone maintenance, but that effect has not been observed in all programs.48 There is an urgent need to increase the availability of methadone and/or buprenorphine substitution treatment wherever there is ongoing injection drug use, and to encourage patients to accept this approach to relieving the health and social burdens of their addiction. A recent study in 24 developing countries found that out of 9.2 million injecting drug users, only 33,000 had access to drug substitution programs.1 From a medical and public health perspective, all injecting drug users must have access to both NSE programs and drug substitution programs, as well as accessible Narcotics Anonymous treatment for those who want to stop.

INCARCERATION
It is impossible to talk about injection drug use and HIV without acknowledging the role of incarceration and prisons in fueling these twin epidemics. Injecting drug users are at great risk of being incarcerated for drug-related offenses or for engaging in illegal activities to obtain money for drugs. That leads to a high concentration of people living with or at high risk of HIV infection in prisons, where conditions are often

<sup>a</sup>Panel on Antiretroviral Guidelines for Adults and Adolescents (Tables 22a, 22b, 22c).<sup>39</sup>
<sup>b</sup>Bruce et al.<sup>40</sup>
characterized by overcrowding, poor sanitation, inadequate medical care, injection drug use, and coercive sexual activity. When HIV infections are acquired in prison, the impact extends beyond the infected individual to his or her family and community upon release.

There is much that can be done to extend HIV prevention and treatment services into the prison setting through the extension of risk-reduction interventions and continuity of care for injecting drug users. Providing access to ART for HIV-infected individuals in correctional facilities is both necessary and feasible; when provided with care and access to medications, inmates who inject drugs respond well to ARV treatment, with adherence rates as high or higher than in the general population. The challenge is to sustain the gains in health status achieved during incarceration once a prisoner is released. That can be achieved through careful discharge planning and the creation of linkages with community care providers. The unmet demand for drug treatment programs in prisons represents an opportunity to implement substitution therapy, providing an alternative to illegal drug use while building a bridge to a mix of social services and support upon release.

**CONCLUSION**

Medical providers and the public health community have a vital part to play in recognizing the role of injection drug use in the expansion of the HIV epidemic, both locally and globally. Injecting drug users represent both a prevention opportunity through the use of needle-exchange and harm-reduction services and a treatment need for those who are already infected. The unique legal constraints facing active drug users often preclude their entry into and retention in medical, social, and psychiatric care services. Drug dependence is a complex medical and psychiatric condition often characterized by relapses, which can challenge and frustrate those working to help individuals overcome their addictions. Yet injecting drug users deserve to be afforded the same dignity, treatment, and support as HIV-positive non-injecting drug users, so that they may live full lives and protect their health and the health of their families and social networks. The critical role injecting drug users play in moving the virus into the general population must be acknowledged and aggressively responded to with a multidisciplinary approach supported by local ministries of health and civil society.

HIV/AIDS and Nutrition in the Era of Antiretroviral Therapy: Programmatic Implications for Care and Treatment

Julia L. Finkelstein, Ferdinand M. Mugusi, Saurabh Mehta, and Wafaie W. Fawzi

The HIV pandemic continues to have a pronounced global impact on human health and development, particularly among the world’s poorest and most vulnerable populations. In resource-limited settings, chronic underlying malnutrition and its intersection with food insecurity, poverty, and co-infections pose a serious threat to efforts to combat HIV/AIDS. People living with HIV in resource-limited settings often cite food availability and security as their most immediate and critical concerns; at the same time, governments in developing countries grapple with a range of long-term programmatic, policy, and resource challenges relating to health, food, nutrition, and HIV/AIDS. The dual burden of HIV and malnutrition has a detrimental impact on population health and represents a significant challenge for healthcare professionals in these impoverished settings.

In developing countries, a high prevalence of HIV and malnutrition results in a vicious cycle of undernutrition, poverty, and disease. HIV increases metabolic needs, reduces appetite and dietary intake, and interferes with digestion and nutrient absorption. Poorer nutritional status affects the severity of HIV-related symptoms, immune reconstitution, disease progression, and survival. HIV/AIDS and undernutrition also lead to poverty and lowered nutritional status by reducing health resources, individual work capacity, agricultural and economic productivity, food security, and economic livelihood.

In the context of the rapid scale-up of antiretroviral therapy (ART) in resource-limited settings, an increased focus on nutritional management is urgently required to address the needs of people living with HIV. Among HIV-positive individuals at pre-ART disease stages, nutritional interventions can delay HIV disease progression, prolong survival, improve nutritional status and overall health, and mitigate the metabolic consequences of HIV infection. Nutritional interventions may also delay the onset of AIDS and ART initiation, thereby preserving first-line medications for use later in the course of disease. Similarly, nutritional management is an important adjunct to ART; improved nutritional status may confer benefits to ART safety and efficacy, limit the occurrence of side effects, and improve adherence to antiretroviral (ARV) regimens, patient survival, and quality of life.
HIV AND NUTRITION

The overlapping pandemics of HIV/AIDS and undernutrition have a severe impact on population health in resource-limited settings. According to the United Nations World Food Program, in 2008, an estimated 6.4 million people living with HIV were in need of nutritional support and HIV/AIDS care (i.e., ART, prevention of mother-to-child transmission [MTCT], assistance for orphans and vulnerable children, and palliative care); almost one million people urgently need food aid and ART. The estimated cost of nutritional support for HIV-positive individuals is relatively low, representing just 2% of the total estimated budget needed to target the HIV/AIDS pandemic.1,2

The interrelationship between HIV/AIDS and nutrition is dynamic and complex. HIV/AIDS is characterized by a progressive deterioration in immune function, while malnutrition, both in the form of protein-energy malnutrition and micronutrient deficiencies, also plays a major role in the etiology of immune dysfunction.3,4 Nutritional supplementation, due to its ability to improve humoral and cell-mediated immune function, may be effective in reducing morbidity in HIV-positive patients and decreasing vertical transmission. Improvements in immunological and nutritional status may also help to slow HIV disease progression and reduce the occurrence of opportunistic infections while improving the overall quality of life, an area of increasing importance, as HIV is becoming a manageable chronic disease.

HIV infection adversely affects nutritional status via several mechanisms, such as decreased appetite and food intake, increased caloric requirements (particularly during the symptomatic phase), greater nutrient utilization, and reduced nutrient absorption and bioavailability. Conversely, malnutrition is a risk factor for HIV transmission, disease progression, and mortality. For example, HIV-positive individuals who are severely malnourished at initiation of ART are six times more likely to die compared to those with adequate nutritional status.5 Undernutrition may also interfere with the safety and efficacy of ART and promote the rapid onset of full-blown AIDS.

Nutritional management is integral to comprehensive HIV care and treatment. Improved nutritional status and weight gain can lead to increased strength and enable patients to resume their normal daily activities, including attendance at work and caring for dependents. Increased mortality within the first three months of ART initiation, and concerns regarding ARV adherence, drug resistance, and side effects, reinforce the need for nutritional management. Additionally, the current treatment protocols for ART are associated with several metabolic complications, such as lipodystrophy, which can amplify the adverse effects of HIV infection on nutritional status.

NUTRITIONAL ASSESSMENT

Nutritional assessment is an integral component of nutritional management and HIV/AIDS care and treatment. Accurate, affordable, and feasible nutritional assessment methods are essential to program implementation. A comprehensive evaluation of nutritional status is composed of four main elements: (1) anthropometric assessment, including weight, height, and body composition; (2) biochemical measurements, including serum proteins, lipids, micronutrients, and immunological parameters; (3) clinical evaluation, including a comprehensive medical history and physical examination; and (4) dietary intake assessment.

Anthropometric Assessment

Anthropometric measurements are noninvasive, relatively low cost, and interpretable methods to assess nutritional status. The conventional anthropometric measures of weight, height, body mass index (BMI, kg/m²), and arm circumference can
be accurately measured with minimal training and expense, in even the most resource-limited settings. BMI and weight changes over time are particularly important for nutritional assessment of HIV-positive individuals, since these measures determine the clinical stage of disease and predict survival time. Use of the mid-upper-arm circumference (MUAC) index should be considered, particularly in situations in which it is difficult to collect weight and height, as it offers the operational advantage of being easily portable. However, there is a relatively large variability in MUAC measurements and an increased need for training and standardization of assessments. Accuracy of anthropometric measurements is also influenced by the type, condition, and calibration of the equipment, as well as the training of the individuals conducting the assessment.

Body composition assessment is particularly important in HIV-positive individuals, as both HIV disease and ART are associated with changes in body composition and metabolic complications. Since weight and BMI are crude measures of body composition, assessment necessitates the use of more sophisticated techniques. However, optimal methods to assess body composition, such as dual energy X-ray absorptiometry (DEXA) scans, are prohibitively expensive and operationally challenging to implement in resource-limited settings.

Bioelectrical impedance analysis (BIA) is a comparatively easier and less expensive method to assess body composition. Since BIA devices became available in the 1980s, this tool has become popular due to its ease of use, portability, and relatively low cost compared to other methods of body composition assessment. BIA relies on the difference in electrical conductance by fat and lean tissues to determine body composition after weight, height, sex, and age have been determined. BIA determines the opposition to the flow of an electric current (electrical impedance) of body tissues; electrical impedance can be used to estimate total body water, fat-free body mass, and body fat.

BIA has been used in HIV-positive populations, and BIA measurements have been shown to correlate with survival among people living with HIV. However, some data suggest that these measurements may not accurately reflect body composition in the context of HIV infection, and BIA has not yet been extensively validated in the era of ART. A recent pilot study was conducted to compare BIA, skinfold measurements, and DEXA methods to estimate percentage of body fat mass among 47 HIV-positive men receiving ART. Findings suggested that the level of bias and error in BIA and skinfold methods was relatively low compared to DEXA, and authors concluded that these techniques were acceptable methods of monitoring total body fat mass in HIV-positive male participants on ART. Further research is warranted to determine whether these findings are generalizable to women and children and to resource-limited settings.

Other anthropometric methods of assessing fat distribution include measurement of waist and hip circumferences, waist-to-hip ratio, and triceps skinfold thickness.

Biochemical Measurements
Biochemical measurements, including serum levels of proteins, lipids, micronutrients, and immunological parameters, represent important indicators of nutritional status and serve as valuable guides for clinical management of HIV and malnutrition. Among HIV-positive individuals, serum levels of albumin and vitamin A have been most extensively evaluated. The relative strengths and limitations of these methods are discussed in detail elsewhere.

Clinical Evaluation
Clinical evaluation, including a detailed medical history and physical examination, is essential in the assessment of nutritional status and overall health.
A comprehensive clinical evaluation includes history of weight changes, protein-energy malnutrition, micronutrient deficiencies, intercurrent illnesses, psychosocial health, level of functioning, and quality of life.

**Dietary Intake Assessment**
Dietary intake is optimally assessed by the use of food frequency questionnaires (FFQs), particularly for long-term evaluation. FFQs have been validated in studies in developed countries and in selected developing-country settings, and have become a well-established method of dietary assessment. However, FFQs have not been validated in all resource-limited settings, which may reduce their application. Self-reported dietary recall and diet record methods are useful for short-term dietary intake assessment, but may be more expensive to administer and require high levels of literacy. The relative advantages and disadvantages of these methods are reviewed in detail elsewhere.13,14

**HIV AND MACRONUTRIENT DEFICIENCIES**
Macronutrient malnutrition is common in HIV-positive individuals and is associated with accelerated disease progression, increased morbidity, and reduced survival. The following section reviews the effects of HIV/AIDS on weight loss and growth failure, metabolic disturbances, protein requirements, and fat metabolism.

**Weight Loss and Growth Failure**
HIV/AIDS was referred to as “slim disease” in many parts of Africa at the onset of the pandemic, due to the severe weight loss associated with it. Wasting, the hallmark of HIV disease in adults, is defined as involuntary loss of either 10% of body weight over 12 months, 7.5% over six months, or 5% over three months.15,16 Resting energy expenditure is approximately 10% higher in adults with asymptomatic HIV, compared with HIV-negative individuals; this increase is severalfold higher for individuals with active disease and secondary infections, and among children.17-23

**Weight Loss in Adults**
Weight loss can adversely affect HIV-related health outcomes and survival, particularly in adults at pre-ART disease stages. In a study in Gambia, BMI was a strong independent predictor of survival among HIV-positive patients.24 Baseline BMI of less than 18 kg/m² was associated with a 2.5-fold increase in risk of mortality, after adjusting for age, sex, wasting at diagnosis, baseline CD4 lymphocyte count, tuberculosis, and cotrimoxazole prophylaxis. Weight loss during the first four weeks of ART was also associated with increased risk of mortality in this study. Additionally, among HIV-positive individuals at pre-ART disease stages, as little as 5% weight loss has been associated with increased risk of opportunistic infections, hospitalizations, and mortality. BMI and changes in weight also determine the clinical stage of HIV disease and affect timing and initiation of ART.25-28

**Growth Failure in Children**
HIV infection is associated with poorer growth and development among infants and children. In a prospective cohort study of pregnant women (318 HIV-positive, 309 HIV-negative) and their infants in Rwanda, HIV-positive infants had significantly lower birth weight, head circumference, and weight-to-head circumference ratio at birth, compared to infants who were HIV-negative.29 Several studies in Africa have also found significant delays in linear and ponderal (weight-related) growth in HIV-positive infants less than two years of age.30-35 In a study of pre-pubertal male hemophiliacs, asymptomatic carriers of HIV were one quartile shorter in height for age, compared to HIV-negative children.36
Growth failure is also a powerful predictor of mortality in HIV-positive children, in studies in Malawi, Uganda, and Rwanda. In a study in Tanzania, wasting was an independent predictor of mortality among HIV-positive children but not among HIV-negative children.28

Pathogenesis of Wasting and Growth Failure

The etiology of wasting and growth failure in HIV/AIDS is complex; HIV may contribute to severe weight loss and deficits in growth via several mechanisms, including decreased dietary intake, reduced absorption and bioavailability of nutrients, and increased resting energy expenditure and metabolic demands.

Reduced dietary intake is likely the major contributor to weight loss and wasting in HIV disease in adults39 and growth failure in HIV-positive children.40 Decreased intake and appetite loss may be due to metabolic consequences of HIV disease,41 opportunistic infections (particularly those affecting the oropharynx and gastrointestinal tract), and repeated infections.28 Reduced dietary intake may also be due to poverty-related conditions such as inadequate food intake, food insecurity, decreased agricultural productivity, lack of resources for food preparation and storage, and poor social support at mealtime. The burden of HIV/AIDS is disproportionately higher in the low-income countries, where unhygienic conditions, overcrowding, and infectious diseases are prevalent; these factors increase the likelihood of exposure to repeated infections and further reduce appetite, food security, and dietary intake.

Reduced absorption and bioavailability of nutrients also contribute to weight loss and growth failure, due to intestinal dysfunction and HIV enteropathy. Diarrhea and intestinal malabsorption contribute to the chronic weight loss observed in people living with HIV, due to secondary infections, such as cryptosporidiosis.42-49 Further, HIV may have a direct effect on the intestinal surface and villi, thus altering intestinal absorption and transit.28

Increased metabolic demands associated with HIV infection also contribute to weight loss and growth failure. For example, HIV increases resting energy expenditure, protein turnover, caloric needs, and nutrient utilization. Increased metabolic requirements are also the result of opportunistic infections, other concurrent infections (e.g., malaria and other parasitic diseases), and hormonal deficiencies.

Metabolic disturbances that lead to wasting appear to represent an adaptive response to a generalized inflammatory state, and are mediated by increased secretion of pro-inflammatory cytokines, including tumor necrosis factor (TNF-α), interferon gamma (INF-γ), and interleukins (IL) 1 and 6.50,51 Both TNF-α and INF-γ are known to inhibit myosin expression in muscle cells,52 and TNF-α also induces anorexia.53

Maternal HIV infection also affects fetal growth and development. In a meta-analysis of 17 studies, the risk of low birth weight was twofold higher among infants born to HIV-positive women, compared to infants born to HIV-negative women.54 A recent study in Nigeria found a fivefold higher risk of low birth weight among infants born to HIV-positive women (P<0.0001).55

Reduced dietary intake is likely the major contributor to growth failure in HIV-positive children. In particular, decreased protein intake and increased nutritional requirements during childhood may exacerbate the risk of growth failure. Nutritional deficiencies and related infectious diseases, such as persistent diarrhea, fever, and pneumonia, are also more prevalent in HIV-positive children, further contributing to deficits in growth and development. Social factors, such as parental smoking or illicit drug use during pregnancy, may increase the risk of growth failure in HIV-positive
Micronutrient deficiencies are widely prevalent in HIV-positive populations. In cross-sectional studies, low serum concentrations of various micronutrients have been observed in people living with HIV; injecting drug users, pregnant women, and children seem to be at the highest risk of micronutrient deficiencies. Low serum levels of vitamin A, provitamin A carotenoids, niacin, vitamin B-6, folate, vitamin B-12, vitamin C, vitamin D, vitamin E, iron, zinc, selenium, and magnesium have been well documented.

Micronutrient deficiencies impair systemic immune function, and may accelerate disease progression and increase the risk of vertical transmission. Improved micronutrient status may confer benefits with regard to humoral and cell-mediated immunity, disease progression, and immune reconstitution. Micronutrient supplements can delay disease progression and reduce mortality, particularly among HIV-positive individuals at pre-ART disease stages. Nutritional supplementation may also prolong the pre-ART stage in HIV-positive patients and preserve first-line ART regimens for later use. In the context of ART, improved micronutrient status may also reduce the occurrence of adverse events, mitigate the impact of ART on nutritional outcomes, and improve ART adherence.

**HIV Seroconversion**

A few observational studies have been conducted to examine the role of vitamin A in heterosexual transmission of HIV in resource-limited settings. In a nested case-control study in Rwanda, low serum levels of vitamin A, carotenoid, or vitamin E were not associated with risk of HIV seroconversion. Similarly, a nested case-control study in Tanzania found no significant relationship between vitamin A levels and risk of HIV infection. However, findings from other observational studies have been divergent. Low serum vitamin A and carotenoid levels were associated with increased risk of HIV infection in India. In contrast, low vitamin A levels were protective for HIV seroconversion in a study in Kenya.

**HIV Disease Progression**

Several observational studies have been conducted to examine the role of micronutrients in...
HIV disease progression and immune reconstitution. In the United States, two cohorts were established to assess HIV disease progression in relation to multiple factors, including vitamin intake: the Multicenter AIDS Cohort Study (MACS)^97-100 and the San Francisco Men’s Health Study (SFMHS)^101; nutrient intake was assessed using FFQs. Investigators examined the relationships of various micronutrients with HIV disease progression to clinical AIDS^98,101 and death. In the MACS cohort, a U-shaped relationship was observed between vitamin A intake and HIV disease progression and mortality, whereas in SFMHS, vitamin A intake was directly associated with CD4 lymphocyte counts without any apparent effect on clinical progression. However, B-vitamin intake and/or supplementation in MACS and multivitamin use in SFMHS were associated with reduced risks of disease progression and mortality. Similar benefits of B-complex vitamin supplementation on disease progression and death were observed in a large cohort of 2,179 HIV-positive patients in South Africa.102

Other observational studies have examined the relationships between serum micronutrient levels and HIV disease progression and mortality. Low serum vitamin A was associated with low CD4 counts,83,103-105 accelerated disease progression,105 and increased mortality.103,104,106 Reduced serum vitamin D (1,25-dihydroxyvitamin D) was also associated with low CD4 counts84,107 and increased risk of mortality84 in studies in Germany and Norway, respectively. Lower maternal plasma selenium levels were associated with significantly increased risk of mortality in HIV-positive pregnant women in Tanzania.108

**Maternal and Child Health Outcomes**

Several observational studies have been conducted in sub-Saharan Africa to examine the role of micronutrients in MTCT of HIV and other perinatal outcomes. Low maternal vitamin A status was associated with increased risk of vertical transmission and other adverse pregnancy outcomes in studies in Malawi^100,110 and Rwanda. However, findings regarding maternal vitamin A status and pregnancy outcomes in the United States have been divergent. Low maternal vitamin A levels were associated with increased risk of vertical HIV transmission in one study in the United States.112 However, in other studies no associations were observed between maternal serum levels of vitamin A,113,114 beta-carotene,113 or vitamin E113 and risk of vertical HIV transmission.

In an observational study in Haiti, lower serum zinc levels were associated with increased risk of vertical HIV transmission, although this finding was not statistically significant.115 Low maternal selenium status was also associated with increased risk of intrapartum HIV transmission, fetal death, and child mortality in a study in Tanzania. In an observational study in Uganda, low serum vitamin A and carotenoid concentrations were associated with reduced weight and height velocities in HIV-positive children, suggesting a role for these micronutrients in child growth in the context of HIV.117

It should be noted that observational studies have a few limitations that warrant caution when interpreting findings. The observed associations between micronutrient deficiencies and adverse HIV-related outcomes may be due to reverse causation. For example, HIV infection may lead to decreased nutrient absorption and increased excretion, resulting in lower serum micronutrient levels and an apparent deficiency. Reduced levels of micronutrients may also be attributable to the acute phase response to infection rather than being a marker of actual micronutrient status. There may also be residual confounding due to factors not accounted for in the study design or analyses, such as other nutritional deficiencies, micronutrient supplement use, opportunistic infections, other
coinfections, and access to health care. Therefore, residual confounding of the relationship between micronutrient status and outcomes by these covariates may lead to biased results and constrain interpretability of findings.

**NUTRITIONAL INTERVENTIONS IN HIV-POSITIVE POPULATIONS**

The findings and limitations of the aforementioned observational studies prompted the undertaking of several intervention studies to investigate the effects of micronutrient and macronutrient supplementation on health outcomes in HIV-positive populations.

**Macronutrient-Based Interventions**

The efficacy of macronutrient-based interventions in improving HIV-related outcomes has been examined in several studies. Many of these interventions have focused on providing protein or amino acid supplements to HIV-positive patients.

In a study in France, a complete amino acid infusion was administered to HIV-positive patients; the authors found that deficiencies of essential amino acids (threonine and methionine) were a limiting factor for whole-body protein synthesis. A similar study in Brazil focused on the role of glutamine, an amino acid mobilized from muscle tissue in states of severe stress or catabolic states as an energy substrate; low levels of glutamine were correlated with increased morbidity and mortality among HIV-positive individuals. In another study, 41 HIV-positive adults were randomized to glutamine, alanyl-glutamine, or placebo supplementation; glutamine and alanyl-glutamine both significantly reduced the occurrence of gastrointestinal symptoms and increased the levels of ART medications, compared with the placebo.

A study in Germany found that supplementation with whey proteins led to a sustained increase in glutathione levels in HIV-positive patients. In a randomized trial in Zambia, the effect of amino acid supplementation on health outcomes was examined among children. In this study, 200 children (106 HIV-positive, 94 HIV-negative) with persistent diarrhea-malnutrition syndrome were randomized to receive either an exclusive diet of amino-acid-based elemental feed or standard nutritional rehabilitation (based on skim milk and soya) for four weeks. Significant improvements in weight gain and hemoglobin levels were observed in the elemental feed group; however, there were no differences in mortality between the two groups.

Interventions in several other studies have involved a dietary counseling component, either alone or in combination with a macronutrient supplement. In a study in the United States, investigators conducted a retrospective chart review for 119 HIV-positive patients, to examine the effect of a macronutrient intervention on nutritional status. The intervention included a dietary assessment, intake analysis, appropriate counseling, follow-up, and provision of supplements as needed. Patients who received the intervention had a significantly greater average weight gain, of 0.5 (±5.2) kilograms, while patients who did not receive the intervention lost an average of 1.6 (±5.8) kilograms (P= .02). In another study in the United States, dietary counseling was provided to 17 HIV-positive patients; counseling consisted of recommendations to consume a high-protein diet (1.5g/kg ideal body weight) and at least one high-energy, high-protein nutrition supplement daily. A total of 12 of the 17 patients gained or maintained their weight, leading the authors to propose that a nutritional supplement containing high levels of energy, protein, and nutrients should be the first-line nutrition treatment for malnourished, HIV-positive patients.

In a study in Spain, 74 HIV-positive patients were randomized to receive standard enteral formula (54.5% carbohydrate, 31.5% fat, and 14% protein) or an enterotrophic peptide-based formula,
enriched with omega-3 fatty acids and dietary fiber (65.5% carbohydrate, 15.8% fat, 18.7% protein, 9.46 g/mL omega-3 fatty acids, 8.9 g/L dietary fiber); all patients also received dietary counseling. A significant and sustained increase in weight was observed in both groups after three months. Furthermore, a significant increase in CD4 counts was observed in the group supplemented with the enterotrophic peptide-based formula, but not in the standard formula group.126

In Switzerland, 15 HIV-positive individuals with a BMI of less than 21 kg/m² or a CD4 count under 500 cells/µL were randomized to receive either (1) oral nutritional supplements (complete macronutrient and micronutrient supplementation; 2,510 kJ [~600 kcal]) and dietary counseling or (2) standard of care follow-up, which included identical clinical monitoring but no supplements or specific nutritional advice. In the intervention group, protein catabolism and whole-body protein turnover significantly decreased, as marked by leucine oxidation and whole-body leucine flux, respectively. Lean body mass increased in the intervention group, whereas fat mass decreased, compared to the control group.127

In a placebo-controlled randomized trial in the United States, 68 HIV-positive patients with a history of at least a 5% weight loss in the past three months were randomly assigned to receive either a nutrient mixture or placebo daily for eight weeks. The nutritional supplement consisted of beta-hydroxy beta-methylbutyrate, glutamine, and arginine, and was expected to slow muscle proteolysis. Patients in the intervention group had significantly greater weight gain, increased CD3 and CD8 counts, and lower viral load, compared to the placebo group.128 In a similar study in Chile, 46 HIV-positive malnourished adult outpatients were randomized to receive either a polymeric diet or regular foods for two consecutive 45-day periods, using a crossover design. Weight, fat-free mass, energy balance, and nitrogen balance increased significantly with the polymeric mixture, compared with the standard diet; however, there were no effects on CD4 or CD8 counts or plasma albumin levels.129

A few studies have explored the effect of anabolic hormones on the marked catabolic state associated with HIV infection. Miller et al reported a positive effect of testosterone on body composition in HIV-positive women with AIDS wasting syndrome.130 A large multicenter randomized trial was conducted to examine the impact of recombinant human growth hormone (rhGH) (daily vs. alternate day vs. placebo; dose: 0.1 mg/kg) on treatment of wasting and weight loss, among HIV-positive men and women on ART (88%). A total of 757 participants were randomized across 56 sites in eight countries; 548 individuals were included in the final analyses. Over the 12-week course of therapy, daily rhGH was superior to the placebo in improving physical function (P<.0001), body weight (P<.0001), body composition (P<.0001), and quality of life.131

Findings from randomized trials regarding the effect of anabolic steroids on lean body mass have been inconsistent. A systematic review of eight randomized trials found that testosterone therapy may increase lean body mass in HIV-positive patients.132 However, findings from other trials suggest that anabolic steroids may not confer any benefit to lean body mass in the context of HIV. For example, in a multicenter placebo-controlled randomized trial (14 AIDS clinical trial units), 79 HIV-positive men with at least a 5% weight loss or a BMI of less than 20 kg/m² were randomized to receive megestrol acetate (800 mg) plus testosterone enanathate (200 mg) or megestrol acetate alone, biweekly, for a 12-week period. Increases in weight, lean body mass, and fat were observed in both groups; co-administration of testosterone did not enhance accrual of lean body mass but preserved
sexual functioning.\textsuperscript{133} A placebo-controlled randomized trial was conducted in the United States among HIV-positive women with more than 5% weight loss in the past six months and low testosterone levels (<33 ng/dl); investigators did not observe any improvements in whole-body fat mass, regional fat distribution, insulin sensitivity, or markers of inflammation and thrombolysis with testosterone therapy.\textsuperscript{134}

In a more recent Cochrane review of 13 trials, administration of anabolic steroids resulted in a small increase in lean body mass and body weight, compared with the placebo. However, overall findings from the trials were heterogeneous; the authors concluded that there was insufficient scientific evidence to inform treatment recommendations for the use of anabolic steroids in HIV-positive individuals.\textsuperscript{135} Additionally, potential development of adverse events with the long-term use of steroids is a cause for concern.

The role of other macronutrient supplements, such as enzymes and fatty acids, has been examined in several small studies. As part of the Swiss HIV Cohort Study, 64 HIV-positive patients were enrolled in a double-blind randomized controlled trial and followed for six months. All patients received a daily oral nutritional supplement (606 kcal supplemented with vitamins, minerals, and trace elements), and half were randomized to additionally receive arginine (7.4 g) and omega-3 fatty acids (1.7 g). Body weight increased by a similar magnitude in both intervention and control groups.\textsuperscript{136} Another study was conducted in Italy to evaluate the effectiveness of open-label oral pancreatic enzyme therapy on lipid absorption in 24 HIV-positive patients. Pancreatic enzyme supplementation effectively reduced fecal fat loss among HIV-positive individuals with fat malabsorption.\textsuperscript{137} Modest improvements in fat absorption have also been observed with the use of high-fat diets\textsuperscript{138} and probiotics.\textsuperscript{139}

In a recent Cochrane review of macronutrient interventions in HIV-positive populations, macronutrient supplementation, with or without nutritional counseling, resulted in significant increases in energy and protein intake. However, reviewers found no effects of macronutrient supplements on body weight, fat mass, fat-free mass, or CD4 lymphocyte counts.\textsuperscript{140}

### Micronutrient-Based Interventions

Most micronutrient supplementation studies have examined micronutrients’ effect on two primary outcomes: HIV disease progression and perinatal outcomes, including HIV transmission. We discuss these studies in the two sections that follow, according to their primary focus.

#### Effects on HIV Disease Progression

Several intervention trials have been conducted to examine the effect of micronutrients such as beta-carotene; vitamins A, B-complex, C, and E; zinc; and selenium on HIV disease progression, either singly or jointly as part of a multiple micronutrient formulation. Two trials to examine the effect of beta-carotene supplementation on CD4 counts, one conducted in the United States and one in France, found no association.\textsuperscript{141,142} Vitamin A supplementation also had no effect on CD4 counts or viral load in trials in Kenya,\textsuperscript{143} South Africa,\textsuperscript{144} and the United States.\textsuperscript{145,146}

A multicenter clinical trial in Canada randomized 331 patients with AIDS on conventional management to receive either (1) multivitamins alone (including vitamin A and trace elements) or (2) multivitamins plus carotenoids (120,000 IU of carotene; equivalent to 72 mg of beta-carotene) daily. In multivariate analyses, individuals with higher baseline serum carotene concentrations had significantly improved survival ($P=.04$). A statistically non-significant increase in mortality was observed among participants who did not receive carotenoids
supplementation, compared to those who did; this increase became significant after adjustment for baseline CD4 counts and serum carotenoid concentrations \((P=.03)\). However, a major limitation of this study was the markedly reduced potency of the carotenoid supplement administered; authors reported that the daily dose of carotenoids was equivalent to only 9.2 milligrams of beta-carotene, instead of the intended 72 milligrams.

In a zinc supplementation trial in Peru, 159 HIV-positive adults with at least seven days of diarrhea were randomized to receive either zinc (100 mg) or a placebo daily. Zinc supplementation had no effect on either duration (persistence of diarrhea at day 14) or remission (time to cessation) of diarrhea. However, deficient serum zinc concentrations were observed in a high proportion of patients during follow-up (i.e., 66% of supplemented patients and 94% of nonsupplemented patients were deficient). Therefore, the regimen dose, duration, or adherence may have been insufficient to observe any potential beneficial effect of zinc supplementation in this population.

In the Trial of Vitamins study in Tanzania, 1,078 HIV-positive pregnant women were randomized to receive daily supplementation of (1) vitamin A (30 mg beta-carotene and 5,000 IU of preformed vitamin A), (2) multivitamins (20 mg thiamine, 20 mg riboflavin, 25 mg B-6, 100 mg niacin, 50 μg B-12, 500 mg C, 30 mg E, and 0.8 mg folic acid), (3) both vitamin A and multivitamins, or (4) placebo, using a 2-x-2 factorial design. At delivery, women in the vitamin A supplemented groups received an additional oral dose of vitamin A (200,000 IU) (vs. placebo). All women also received iron (120 mg ferrous iron) and folate (5 mg folic acid) supplementation daily. Maternal multivitamin supplementation resulted in significant increases in CD4, CD8, and CD3 counts, and significantly decreased viral load. Multivitamins also delayed the progression of HIV disease to World Health Organization stage IV or AIDS-related death by 30%, and significantly reduced manifestations of HIV disease such as oral thrush, oral ulcers, difficulty in swallowing, fatigue, rash, and acute upper respiratory infections. Multivitamin supplementation demonstrated a protective effect on maternal wasting and improved hematological status \((0.59 \text{ g/dL increase})\) during follow-up \((P=.0002)\), compared with placebo. However, vitamin A had no significant effect on any of these outcomes.

Multiple-micronutrient supplementation had no effect on CD4 counts in randomized trials in Thailand (vitamins A, B-1, B-2, B-6, B-12, C, D, E, and K; beta-carotene; folate; iron; zinc; and selenium) and Zambia (vitamins A, C, and E; selenium; and zinc). However, the trial in Thailand reported a nonsignificant decrease in mortality in the micronutrient supplemented arm; this decline was significant among individuals with CD4 cell counts of less than 100 cells/µL.

In a zinc supplementation trial in Peru, 159 HIV-positive adults with at least seven days of diarrhea were randomized to receive either zinc (100 mg) or a placebo daily. Zinc supplementation had no effect on either duration (persistence of diarrhea at day 14) or remission (time to cessation) of diarrhea. However, deficient serum zinc concentrations were observed in a high proportion of patients during follow-up (i.e., 66% of supplemented patients and 94% of nonsupplemented patients were deficient). Therefore, the regimen dose, duration, or adherence may have been insufficient to observe any potential beneficial effect of zinc supplementation in this population.

Multiple-micronutrient supplementation had no effect on CD4 counts in randomized trials in Thailand (vitamins A, B-1, B-2, B-6, B-12, C, D, E, and K; beta-carotene; folate; iron; zinc; and selenium) and Zambia (vitamins A, C, and E; selenium; and zinc). However, the trial in Thailand reported a nonsignificant decrease in mortality in the micronutrient supplemented arm; this decline was significant among individuals with CD4 cell counts of less than 100 cells/µL.

In the Trial of Vitamins study in Tanzania, 1,078 HIV-positive pregnant women were randomized to receive daily supplementation of (1) vitamin A (30 mg beta-carotene and 5,000 IU of preformed vitamin A), (2) multivitamins (20 mg thiamine, 20 mg riboflavin, 25 mg B-6, 100 mg niacin, 50 μg B-12, 500 mg C, 30 mg E, and 0.8 mg folic acid), (3) both vitamin A and multivitamins, or (4) placebo, using a 2-x-2 factorial design. At delivery, women in the vitamin A supplemented groups received an additional oral dose of vitamin A (200,000 IU) (vs. placebo). All women also received iron (120 mg ferrous iron) and folate (5 mg folic acid) supplementation daily. Maternal multivitamin supplementation resulted in significant increases in CD4, CD8, and CD3 counts, and significantly decreased viral load. Multivitamins also delayed the progression of HIV disease to World Health Organization stage IV or AIDS-related death by 30%, and significantly reduced manifestations of HIV disease such as oral thrush, oral ulcers, difficulty in swallowing, fatigue, rash, and acute upper respiratory infections. Multivitamin supplementation demonstrated a protective effect on maternal wasting and improved hematological status \((0.59 \text{ g/dL increase})\) during follow-up \((P=.0002)\), compared with placebo. However, vitamin A had no significant effect on any of these outcomes.

Multiple-micronutrient supplementation had no effect on CD4 counts in randomized trials in Thailand (vitamins A, B-1, B-2, B-6, B-12, C, D, E, and K; beta-carotene; folate; iron; zinc; and selenium) and Zambia (vitamins A, C, and E; selenium; and zinc). However, the trial in Thailand reported a nonsignificant decrease in mortality in the micronutrient supplemented arm; this decline was significant among individuals with CD4 cell counts of less than 100 cells/µL.
trials used identical multiple-RDA micronutrient supplementation (vitamins B-complex, C, and E), apart from the addition of selenium in the Kenyan trial. The trials in Kenya and Tanzania identified beneficial effects of micronutrient supplementation on CD4 and CD8 counts. However, the Kenyan trial also identified an increased risk of viral shedding with supplementation. Since both trials used identical micronutrient supplementation regimens (except the addition of selenium) and genital viral shedding was greatest among women with normal selenium levels at baseline, the potentially harmful effect on HIV transmission via increased genital viral shedding observed in the Kenya study may be attributable to selenium.

Selenium-only supplementation studies in HIV-positive populations have had divergent findings. A selenium supplementation trial was conducted in Nigeria among individuals with advanced AIDS on ART; patients receiving selenium supplementation had higher rates of CD4 cell increase, fewer hospital visits, and greater weight gain, compared with the patients on ART alone. In a randomized controlled trial among 262 HIV-positive adults, serum selenium concentrations increased significantly in the selenium-treated group, compared with the placebo-supplemented group ($P<.001$). Increased serum selenium levels significantly reduced HIV viral load ($P<.02$) after adjusting for age, sex, ethnicity, income, education, illicit drug use, HIV symptom classification, time since HIV diagnosis, ARV regimen, adherence, and hepatitis C coinfection. Selenium-treated participants whose serum selenium increase was greater than 26.1 µg/L demonstrated excellent treatment adherence, no changes in HIV viral load, and increased CD4 counts. However, in a selenium trial in HIV-positive pregnant women in Tanzania, there were no differences in maternal CD4 counts, plasma viral load, or mortality between selenium- and placebo-supplemented groups.

**Effects on Maternal and Child Health Outcomes**

Randomized trials have primarily focused on the role of vitamin A status in pregnancy outcomes among HIV-positive pregnant women and children. In trials in Malawi and South Africa, maternal vitamin A supplementation did not have any beneficial effect on the risk of MTCT of HIV. However, contrary to a priori hypotheses, maternal vitamin A supplementation significantly increased the risk of vertical HIV transmission in trials in Tanzania and Zimbabwe.

In the ZVITAMBO trial in Zimbabwe, administration of the vitamin A regimen to either the mother (400,000 IU) or infant (50,000 IU) significantly increased the risk of vertical HIV transmission and infant mortality. However, vitamin A administered to both the mother and the infant did not increase the risk of these outcomes, compared with the placebo. Additionally, all three vitamin A regimens resulted in a twofold increase in the risk of mortality among infants who were HIV-negative at six weeks postpartum, compared with the placebo arm ($P\leq.05$).

In a randomized trial in South Africa, 118 infants born to HIV-positive women were randomized to either vitamin A or placebo supplementation. Vitamin A reduced diarrheal morbidity by 50% among HIV-positive infants with diarrhea; no effect was observed in HIV-negative children. In another trial in South Africa among HIV-positive children, vitamin A supplementation prior to influenza vaccination blunted the increase in HIV viral load typically observed post-immunization. In a randomized trial in Tanzania, vitamin A reduced all-cause mortality by 63% and decreased AIDS-related deaths by 68% in HIV-positive children. Vitamin A supplementation was also associated with reduced risk of respiratory infections and increased average length gain in HIV-positive children. A protective effect of vitamin A supplementation on
mortality was also observed among HIV-positive children in a randomized trial in Uganda.\(^{168}\)

Other single-nutrient trials have examined the role of zinc and selenium supplements in maternal and child health outcomes. In a randomized trial in Tanzania, maternal zinc supplementation had no effect on the risk of fetal death, preterm birth, infant low birth weight, vertical HIV transmission, or neonatal mortality.\(^{169,170}\) In a trial in South Africa, HIV-positive children were randomized to receive either oral zinc supplementation or a placebo daily for six months. There were no differences in viral load, CD4 counts, or hemoglobin concentrations in the two groups; however, zinc supplementation reduced the incidence of watery diarrhea.\(^{171}\) In a trial in HIV-positive pregnant women in Tanzania, maternal selenium supplementation had no effect on neonatal or overall infant mortality but reduced the risk of child mortality after six weeks, suggesting a survival benefit for breastfeeding children.\(^{157}\)

In the trial of vitamins study in Tanzania described earlier, maternal multivitamin (vitamins B-complex, C, and E, at multiple-RDA levels) supplementation did not affect the risk of MTCT of HIV in the overall population; however, multivitamins significantly reduced the risk of vertical HIV transmission among infants born to women who were nutritionally and/or immunologically compromised at baseline.\(^{161}\) Maternal multivitamin supplementation also reduced the risk of severe preterm birth by 39%, low birth weight by 44%, small size for gestational age by 43%, and fetal death by 39%.\(^{149}\) In contrast, vitamin A supplementation had no effect on pregnancy outcomes, but increased the risk of vertical HIV transmission by 38%.\(^{161}\)

In the Trial of Vitamins study, multivitamin supplementation significantly increased maternal weight gain and reduced the risk of developing hypertension during pregnancy.\(^{172,173}\) Maternal multivitamin supplementation also improved child psychomotor development and decreased the risk of developmental delay.\(^{174}\) Children born to mothers who received multivitamins also had improved hematological status, with a 63% lower risk of macrocytic anemia, compared with the placebo group (\(P=.01\)).\(^{152}\)

In accordance with WHO guidelines, daily folate and iron supplementation is the standard of prenatal care in most settings, and includes 400 mg folate and 60 to 120 mg iron for a duration of six months, regardless of HIV status.\(^{175}\) These recommendations are based on the demonstrated benefits of folate in preventing neural tube defects\(^{176}\) and of iron in preventing maternal anemia and related complications.\(^{177-180}\)

The safety and efficacy of folate and iron supplementation have not been extensively evaluated in HIV-positive populations. There is a lack of evidence to suggest that folate supplementation should differ among HIV-positive women. However, there are some concerns regarding the safety of iron supplementation in HIV-positive individuals. For example, iron is an acute-phase reactant, akin to vitamin A and zinc, and may therefore have similar adverse effects. Additionally, although there is some evidence to suggest that iron supplementation may exacerbate malaria outcomes, its potential risks for HIV-positive individuals residing in malaria-endemic regions are unknown. Further research is needed to elucidate the role of iron supplementation in HIV-positive individuals and to establish specific iron-folate recommendations for HIV-positive pregnant women and malaria-endemic settings.\(^{181-184}\)

**HIV, NUTRITION, AND ART**

As access to ART is rapidly scaled up worldwide, addressing the role of nutrition in the context of ART is an increasingly critical component of HIV/AIDS care and treatment. Among HIV-positive individuals on ART, enzyme systems (e.g., mixed function oxidase in the liver) and nutrient cofactors...
are essential for efficient metabolism, uptake, and utilization of medications. Malnutrition affects medication absorption, safety, efficacy, and adherence. Nutritional interventions may confer benefits with regard to ART-related side effects and metabolic complications. Conversely, ART may also contribute to further improvements in nutritional status by alterations in appetite, dietary intake, nutrient absorption, metabolism, and excretion. Potential nutrition-ART interactions also warrant consideration in the development of evidence-based HIV/AIDS programs in the ART era.

**Effects of ART on Macronutrient Status**
The occurrence of HIV/AIDS-related wasting appears to have diminished in the ART era; it is postulated that ART reduces HIV-associated weight loss and wasting by decreasing viral load. There is, however, limited evidence regarding the specific impact of ART on macronutrient status at the individual level. For example, a recent study in India found that the majority of HIV-positive patients who received nevirapine-based ART gained weight and retained body shape symmetry with no changes in waist-to-hip ratio; however, several patients lost weight despite initiating ART. Similarly, in an analysis of 469 HIV-positive individuals in the Nutrition for Healthy Living cohort, more than 50% of the cohort was receiving ART at the time that they met clinical criteria for wasting.

Several studies have examined the effect of ART on child growth. Miller et al found that exposure to non-protease-inhibitor ART before three months of age was a risk factor for failure to thrive in HIV-positive infants. Similarly, Goldstein and colleagues found a higher rate of low birth weight in infants born of HIV-positive women who received either zidovudine (AZT) or protease inhibitors (PIs). In contrast, Morris et al found that intrauterine exposure to maternal PI therapy (for the prevention of MTCT of HIV) had no effect on birth outcomes. In utero or neonatal exposure to AZT had no adverse effects on intrauterine and postnatal growth of HIV-negative children followed for up to 5.6 years. Tuomala et al found no association between the use of combination ART and low birth weight. In a study among HIV-positive children, ART positively influenced height and weight, reduced viral load, and increased CD4 cell counts. Most of these studies, however, were conducted in developed countries, where the risk of poor nutrition is relatively low. Furthermore, these studies had methodological limitations that constrain interpretability of findings, including small sample sizes, use of different endpoints and proxy measurements for child growth, and limited assessment of dietary intake and nutritional status.

**Effects of ART on Micronutrient Status**
ART may also alter the micronutrient status of HIV-positive individuals. Abnormalities in zinc and selenium plasma levels were observed following ART initiation in a study in France. Lower levels of circulating vitamin D (1,25D) have also been found in some observational studies and are more commonly reported among individuals on PI therapy. This finding is cause for concern due to the increased occurrence of bone-related disorders with HIV infection, such as osteoporosis, osteopenia, and osteodensity.

**Metabolic Complications of ART**
HIV-positive individuals on long-term ART may experience a variety of metabolic abnormalities. These complications can be severe and fatal, interrupt adherence, and reduce the quality of life of the affected individual. Metabolic complications of ART include fat redistribution, dyslipidemia, insulin resistance, lactic acidemia, mitochondrial toxicity, and abnormalities in bone mineral metabolism. Each class of ARV medication has been associated with metabolic complications;
Abnormalities in fat distribution are common among individuals on ART. Lipodystrophy, the loss of peripheral and subcutaneous fat and accumulation of central fat, is observed within 7 to 22 months after ART initiation in most patients. Men are more likely to accumulate dorsocervical fat (buffalo hump) and present with fat depletion, whereas women more commonly accrue fat in the waist and breasts. In a study in Italy, investigators examined adipose tissue alterations in 2,258 HIV-positive adult men and women; men had a significant 0.47 times lower risk of presenting with adipose tissue alterations compared to women ($P<.0001$).

In a recent observational study in the United States, researchers examined the relationship between dietary intake (four-day food records or 24-hour recall) and serum lipid levels in 356 HIV-positive patients and 162 community-based HIV-negative controls. HIV-positive patients had significantly greater intake of total fat, saturated fat, and cholesterol, and a greater percentage of calories from saturated fat and trans fat, compared to controls at similar levels of caloric intake. Greater saturated fat intake was predictive of increased serum triglyceride levels. In a subsequent analysis, visceral adiposity was increased among nonobese HIV-positive men and women, compared to controls. Abdominal subcutaneous adiposity was reduced in HIV-positive men in normal and overweight categories, but increased among HIV-positive obese women, relative to control participants. Findings were similar when limiting the analysis to individuals without metabolic syndrome.

Lipodystrophy contributes to insulin resistance in HIV-positive patients, and is associated with a constellation of metabolic abnormalities such as impaired glucose tolerance, insulin resistance, and type 2 diabetes. An estimated 6% to 10% of patients receiving ART will develop type 2 diabetes in their lifetime. Conversely, insulin resistance may also be a primary feature underlying the etiology of lipodystrophy syndrome, as it often precedes fat redistribution. ARV medications stavudine, indinavir, ritonavir, and lopinavir, but not atazanavir or amprenavir, are known to acutely induce insulin resistance; however, long-term effects are not known. Several studies have demonstrated the efficacy of insulin-sensitizing medications in lipodystrophy management. A randomized trial was conducted to examine the effects of exercise training and metformin on body composition and cardiovascular indices among HIV-positive patients on ART with hyperinsulinemia and fat redistribution. Findings demonstrated that exercise training in combination with metformin significantly improved cardiovascular and biochemical parameters, compared to metformin alone.

Nucleoside reverse transcriptase inhibitor (NRTI) drugs may lead to a range of adverse metabolic effects, such as fat wasting, peripheral neuropathy, lactic acidosis, cardiomyopathy, and pancreatitis. These diverse NRTI side effects may be mediated by a common physiological mechanism of mitochondrial toxicity. In a case-control study, cases were HIV-positive patients with lactic acidosis or hyperlactatemia; controls were randomly selected (two per case) from treated patients and matched by center and calendar year. After adjusting for age, gender, and current CD4 count, lactic acidosis/hyperlactatemia was associated with exposure to didoxynucleosides and advanced immunosuppression (CD4<200 cells/µL). This association remained across all categories of didanosine exposure but was greatest at shorter durations of exposure (less than 12 months), suggesting a potential susceptibility in a small percentage of HIV-positive individuals. Lactic acidosis, although relatively uncommon, can be potentially life-threatening,
with an estimated 60% mortality rate. This is of particular concern in resource-limited settings where NRTIs are more frequently used, and other risk factors for lactic acidosis (e.g., lower CD4 counts) are likely to be more prevalent. A potential mechanism for the observed decrease in HDL might be the impairment of cholesterol efflux from macrophages by HIV itself, therefore promoting atherosclerosis in HIV-positive patients.

A clinical trial was conducted to compare the effects of three ARV regimens—didanosine (ddI, Videx) and stavudine (d4T, Zerit), plus either efavirenz (Sustiva), nelfinavir (Viracept), or both—on metabolic complications. A total of 234 patients (out of 881) progressed to develop metabolic syndrome, as defined by criteria of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Third Report; ATP-III), and a total of 178 patients met International Diabetes Federation criteria for metabolic syndrome. The development of metabolic syndrome during ART was a significant risk factor for cardiovascular disease and diabetes; however, no significant differences were observed in rates of progression to metabolic syndrome between the randomized treatment arms.

Several studies have been conducted to examine the effects of ART on cardiovascular parameters. In the Strategies for Management of Antiretroviral Therapy (SMART) treatment interruption study, investigators evaluated electrocardiograms of 4,831 HIV-positive patients with no prior ischemic heart disease and found that more than 10% had asymptomatic ischemic heart disease. A marginally significant reduced risk of asymptomatic heart disease was observed in patients who were using a non-nucleoside reverse transcriptase inhibitor (NNRTI) \( (P = .05) \); however, no association was observed between ART duration and asymptomatic ischemic heart disease. In a large prospective observational study of 23,437 HIV-positive patients, longer duration of exposure to PIs was associated with increased risk of myocardial infarction, whereas no such relationship was observed with NNRTIs. Findings were consistent with prior studies that found an increased incidence of coronary artery disease and myocardial infarction in HIV-positive patients receiving ART.

In the context of increased use of ARV medications that have less impact on lipid metabolism, however, the occurrence of ART-related lipodystrophy and cardiovascular risk factors are decreasing. In a recent report from the Swiss HIV Cohort Study, the likelihood of developing lipodystrophy decreased as the percentage of patients receiving stavudine, didanosine, and nelfinavir declined; the percentage taking lopinavir, nevirapine, and efavirenz remained stable; and the percentage taking atazanavir and tenofovir increased. Other factors that may be contributing to this observed decline include the increased use of lipid-lowering drugs and lower prevalence of smoking.

**NUTRITION AND ART: SAFETY, EFFICACY, AND ADHERENCE**

Nutritional interventions may affect the safety and efficacy of ART and enhance adherence. Nutritional interventions may also have beneficial effects on HIV-related outcomes among individuals receiving ART, including reduced rate of disease progression, enhanced immune function, reduced viral load, and decreased mortality. Malnutrition at the time of starting ART has been identified as a significant independent predictor of reduced survival. Additionally, improvements
ARV-food interactions have been reviewed in further detail by Nerad et al.241

In patients receiving ART, micronutrient supplementation may help to correct ART-associated adverse effects. For example, iron may help reduce AZT-associated hematologic toxicity and anemia.242 Vitamin E may help reduce metabolic abnormalities associated with ART, including body fat redistribution, dyslipidemia, insulin resistance, and serum lactate.243 Vitamin B-12 has been identified as a potential adjunct to reduce AZT-associated hematologic toxicity,244 and B-complex vitamins may attenuate NRTI-associated lactic acidosis. Antioxidant supplementation (including vitamin E, beta-carotene, N-acetylcysteine, selenium, gingko biloba extracts, and nutritional supplements) has demonstrated benefits in asymptomatic stable chronic hyperlactatemia in HIV-positive patients taking NRTIs.245 Antioxidants, such as selenium, Vitamin C, and Vitamin E, may also reduce NF-κB activation, which is implicated in viral transcription.

Nutritional interventions and ART may interact through a number of potential mechanisms: (1) nutritional status may affect ART absorption, metabolism, distribution, and excretion; (2) ARVs may affect nutrient absorption, metabolism, distribution, and excretion; (3) ART side effects may reduce dietary intake; and (4) ARVs and certain nutrients may lead to side effects.

Nutrition-ART interactions may adversely affect the safety and efficacy of ART. For example, significantly decreased plasma concentrations of the PI saquinavir were observed in healthy volunteers with long-term use of garlic supplements.256 Decreased cytochrome P450 activity and reduced expression of P glycoprotein were observed with the ingestion of the African potato (Hypoxis hemerocallidea) and Sutherlandia frutescens, which are commonly used for symptom relief in HIV-positive patients in some resource-limited settings. These cofactors are important components of medication transport; therefore, Hypoxis hemerocallidea and Sutherlandia frutescens likely increase ARV toxicity.237,238 St. John’s wort (Hypericum perforatum), a popular herbal supplement, may significantly reduce plasma levels of NNRTIs and PIs.239 Similarly, in a small study in HIV-negative healthy volunteers, concomitant administration of high doses of vitamin C reduced steady-state indinavir plasma concentrations.240

in nutritional status may reduce the occurrence of adverse events associated with ART, including diarrhea, nausea, peripheral neuropathy, anemia, and fatigue, and mitigate ART-related metabolic complications. Reducing the occurrence of these side effects may lead to significant improvements in safety, efficacy, and adherence to ART and enhance survival and overall quality of life. Preservation of first-line regimens would also contribute to improved virological suppression and clinical success and have considerable cost implications in resource-limited settings.

Nutritional management is an integral part of care and treatment of HIV-positive patients on ART. Effective management of macronutrient and micronutrient undernutrition may alleviate ART-related adverse effects. Improved nutritional status and overall health may also have beneficial effects on adherence, immune reconstitution, survival, and quality of life.242 For example, in a randomized trial in Zambia, provision of monthly household food rations (micronutrient-fortified corn-soya blend) to food-insecure HIV-positive patients initiating ART increased adherence by 40%, compared with nonparticipants, although there were no significant differences in weight gain between the two groups.246

The majority of research on ART and its related complications has been conducted in developed countries, among well-nourished HIV-positive individuals. However, some studies have demonstrated
similar adverse effects of ART in less-developed settings. For example, in a cross-sectional study in India, 46% of patients taking first-line ART for more than one year had significant fat redistribution. Dyslipidemia and hyperglycemia were also more commonly reported among HIV-positive patients on ART; lipodystrophy was particularly prevalent among patients receiving stavudine-based ART regimens.\(^2\) This finding is of particular concern, as stavudine is the most widely utilized ART regimen in resource-limited settings, due to its comparatively lower cost.\(^2\)–\(^4\)

**PROGRAMMATIC IMPLICATIONS**

Comprehensive programs that concurrently target HIV/AIDS and nutrition are central to fostering long-term improvements in population health. Essential to this comprehensive approach is the training of health-care providers, community health workers, and caregivers on nutritional assessment, counseling, food-drug interactions, and adherence. It is also critical to involve patients and caregivers in the planning and development of individual nutritional and medication plans. In order to strengthen home- and community-based programs, provision of nutritional tool kits (e.g., dietary plans, medications, and meal schedules) and integration of nutritional management, specific nutritional-ARV interactions, and adherence into nutritional counseling, staff training, and supervision systems are recommended.\(^3\)

Establishment and strengthening of linkages to governmental and nongovernmental actors, as well as the private sector, are needed to develop sustainable, long-term improvements in the health and nutritional status of HIV-positive populations. Forging linkages with nongovernmental organizations and the private sector may ensure that foods and supplements are tailored to meet the specific needs of people living with HIV and are manufactured in-country. Public-private partnerships may also inform the development of cost-effective and sustainable nutritional interventions. To ensure greater food security, it is critical to incorporate poverty alleviation strategies, microfinance opportunities, and intersectoral collaboration, in order to maximize programmatic integration and long-term sustainability.

**NUTRITIONAL ASSESSMENT AND COUNSELING**

Assessment of nutritional status is an essential component of HIV care and treatment and should be conducted as part of routine screenings in HIV/AIDS programs. Some nutritional assessment techniques, such as DEXA, are optimal under controlled environments but remain prohibitively expensive and challenging to implement in field settings. However, even in the most resource-limited contexts, screening for nutritional status can be achieved through assessment of anthropometry (e.g., MUAC), dietary intake, and clinical examinations, with minimal training and financial resource investment. Initial assessment of dietary intake patterns, food security, and type and seasonal availability of local foods should also be paired with an evaluation of individual-level nutritional needs, ARV regimens, and specific nutritional-ART interactions. Although BIA and biochemical methods are excellent measures of body composition and micronutrient status, these assessment techniques are comparatively more resource intensive and pose programmatic and operational challenges for large-scale implementation in developing regions. Additionally, BIA needs to be further validated among HIV-positive populations in resource-limited settings in the ART era.

Nutritional counseling can enable health-care professionals to identify and address barriers to nutritional management. Dietary counseling can also provide information and support to HIV-positive individuals and their caregivers regarding
specific dietary intake, nutritional needs, nutritional requirements of medications, and contraindicated foods, in order to achieve optimal nutritional status and ARV safety and efficacy.

In integrated nutrition and HIV programs, it is important to consider poverty-related factors that fuel the dual epidemics of undernutrition and HIV/AIDS. Consideration of household- and community-level factors such as food security, type and seasonal variation of foods, patterns of household food utilization and distribution, potential gender inequalities, and protection of vulnerable populations should be incorporated into nutritional counseling related interventions.

**NUTRITIONAL INTERVENTIONS FOR PEOPLE LIVING WITH HIV**

In addition to dietary assessment and counseling, nutritional interventions are warranted to meet the nutritional requirements of people living with HIV.

**Adult Men and Women**

Based on current scientific evidence, the major macronutrient recommendation for HIV-positive adults is to increase energy intake by 10% among asymptomatic individuals and by 20% to 30% in symptomatic adults. These energy requirements should be achieved through food-based approaches whenever possible; there is currently no evidence to support specific increases in protein or other macronutrients or for changes in the usual composition of a balanced diet.29

In HIV-positive adults, multivitamin supplementation of vitamins B-complex, C, and E is recommended to slow HIV disease progression and reduce the risk of associated mortality.250 Micronutrient supplementation may also be beneficial as an adjunct to ART. There is currently no conclusive epidemiological evidence to support the specific use of other micronutrient supplements in HIV-positive adults.251

**Pregnant and Lactating Women and Children**

Multivitamin supplementation (vitamins B-complex, C, and E) is strongly recommended for HIV-positive pregnant women, based on its demonstrated effect on pregnancy outcomes, such as low birth weight and fetal death. Vitamin A supplementation should be avoided for HIV-positive pregnant and lactating women, due to the associated increased risk of MTCT as identified in some randomized trials. However, dietary intake of vitamin A by these women should remain adequate and consistent with recommended dietary allowances. In accordance with WHO guidelines, daily folate and iron supplementation is recommended for HIV-positive pregnant women to reduce the risk of neural tube defects, maternal anemia, and other adverse pregnancy outcomes. However, the safety and efficacy of iron supplementation urgently needs to be established in HIV-positive pregnant women.182 There is currently no strong epidemiological evidence to support the use of other micronutrient supplements, such as zinc and selenium, among pregnant and lactating HIV-positive women.252

As per the recommendations of WHO and the Joint United Nations Program on HIV/AIDS (UNAIDS), HIV-positive pregnant women should receive ARV prophylaxis for prevention of MTCT. HIV-positive mothers should avoid breastfeeding “when replacement milk is acceptable, feasible, affordable, sustainable and safe.”253,254 In settings where alternatives to breastfeeding are not viable, exclusive short-course (six month) breastfeeding and early weaning are recommended, followed by appropriate introduction of complementary foods; mixed feeding is to be avoided.

Children represent another vulnerable group warranting particular attention in the context of HIV and nutrition. Adequate nutritional support for HIV-positive children is 20% to 30% greater than the total energy intake requirements for
HIV-negative children. Vitamin A supplementation should be avoided in the first months of life, due to increased risk of MTCT of HIV. However, periodic vitamin A supplementation for children older than six months (preferably at the time of early weaning) is recommended regardless of infant HIV status, based on its benefits in reducing all-cause morbidity and mortality.\textsuperscript{255} Nutritional support for the infant (e.g., micronutrient-fortified foods) is also suggested, starting at the time of early weaning through 30 months of age, in order to reduce the risk of stunting.

**Monitoring and Evaluation**

Monitoring and evaluation are essential to effective delivery of nutrition and HIV/AIDS services. Food aid programs are currently being implemented in many developing countries, with a focus on the provision of nutritional support for people living with HIV; however, there is limited scientific evidence to support the nutritional composition of many of these interventions and a lack of evaluation of these food aid programs. This poses challenges to the development of recommendations for universal nutritional programs for a broad range of contexts.\textsuperscript{256} Incorporation of operational research initiatives and program evaluation are needed to provide a stronger evidence base for integrated HIV and nutrition programs, and to inform effective delivery of services to HIV-positive populations in resource-poor settings.

**RESEARCH GAPS AND FUTURE DIRECTIONS**

There is a paucity of evidence-based interventions that concurrently target HIV and undernutrition among individuals on ART in developing countries. Most nutritional intervention studies to date have been conducted in developed countries and among HIV-positive patients with relatively better immunological and nutritional profiles. Studies have been characterized by methodological limitations such as small sample sizes, short duration of follow-up, lack of nutritional supplementation, and inadequate assessment of HIV-related outcomes.

There is an urgent need for clinical, epidemiological, and operational research on nutrition and HIV/AIDS in the ART era to inform HIV/AIDS care and treatment in resource-limited settings. Specific nutritional recommendations are needed for HIV-positive adults at pre-ART disease stages and for individuals on ART. The effect of nutritional interventions on ART safety and efficacy needs to be evaluated to ensure ART adherence, quality of life, long-term retention, and survival in HIV/AIDS care and treatment programs.

Areas for further research include nutrition and HIV, nutrition-pharmacological interactions, and vulnerable populations, such as pregnant and lactating women and children.

**Nutrition and HIV**

- Further research is warranted to establish the appropriate nutritional content and form of aid that can be provided to people living with HIV in resource-limited settings. Dietary supplements using a range of locally available foodstuffs are needed to overcome severe weight and nutritional loss during acute illness.
- Research is needed to develop palatable, affordable, available, and acceptable nutritional interventions, with ongoing feedback from individuals, caregivers, and health professionals. Identification of locally appropriate, sustainable methods of increasing dietary intake to meet the additional energy and micronutrient requirements of HIV-positive individuals in resource-limited settings is also needed.
- Further research is warranted to determine if specific protein or amino-acid-based interventions are efficacious in reducing morbidity and mortality among HIV-positive individuals.
Specifically, additional research is needed to elucidate the role of particular proteins or amino acids, including threonine, methionine, and glutamine, in HIV-positive patients.

- Additional research is needed to evaluate the potential long-term benefits and adverse effects of anabolic steroids, optimal doses, and methods of administration. Furthermore, the correlation of improved lean body mass with more clinically relevant endpoints, such as physical functioning, morbidity, and mortality, needs to be determined.\(^\text{135}\)

- There is insufficient evidence regarding the relative benefit of administering single versus multiple RDA levels of micronutrients to HIV-positive individuals or the exact doses required. Although multiple-RDA multivitamin supplementation (including B-complex, C, and E) has demonstrated a consistent beneficial effect on immunological function among HIV-positive individuals, the generalizability of findings to HIV-positive individuals on ART has not yet been established.

- Due to concerns regarding iron supplementation among HIV-positive individuals, the efficacy and safety of routine iron supplementation—in HIV-positive individuals in general and in HIV-positive pregnant women in particular—urgently needs to be examined.

- Additional research is warranted to examine interactions between foods and nutrients among of HIV-positive individuals on ART. Micronutrients can have synergistic or antagonistic effects; for example, iron supplements may decrease zinc absorption,\(^\text{257,258}\) and high doses of zinc can interfere with the absorption of iron and copper.\(^\text{259,260}\) Further research is warranted to examine nutrient-nutrient interactions and evaluate complementary dietary approaches, such as food fortification as adjuncts to ART and nutritional supplementation.

### Nutrition-Pharmacological Interactions

- Additional research is warranted to develop evidence-based recommendations for specific nutrition-pharmacological interactions, and consideration of the role of traditional medicine and local diets in these settings. Greater understanding of the interactions between ARVs and traditional medicines will help to promote optimal medication safety and efficacy and to reduce the risk of adverse interactions and side effects.

- The generalizability of findings in the aforementioned studies, which have primarily been conducted in developed countries, to resource-limited settings characterized by chronic undernutrition has not been established. The effects of preexisting nutritional deficits on ARV safety and efficacy and the metabolism of nutrients and ARVs are unknown. Malnutrition may adversely affect the efficacy of certain ARVs; therefore, specific nutritional interventions may play a profound role in mitigating these effects. Conversely, the impact of ARVs on the nutritional and immunological status of chronically malnourished individuals has not been well documented.

- There are limited data regarding the prevalence of metabolic complications in long-term use of ART in resource-limited settings. However, as ART access is scaled up in these settings and the average lifespan of HIV-positive individuals increases, there is growing need for evidence regarding prevention, diagnosis, and management of the metabolic consequences of ART. Many metabolic complications associated with ART may potentially be corrected with nutritional modifications; for example, a high-fiber diet may help with improving lipodystrophy, and vitamin D and calcium supplementation may help to correct derangements in bone mineral metabolism.
Vulnerable Populations: Pregnant and Lactating Women and Children

- Additional research is needed regarding nutrition and ART in HIV-positive pregnant women; specifically, the potential impact of ART on the nutritional needs of pregnant women and the optimal nutritional supplementation during pregnancy. There is insufficient evidence to suggest that iron-folate recommendations should differ for HIV-positive pregnant women; however, the safety and efficacy of iron supplementation among HIV-positive pregnant women needs to be established.

- Additional research is needed regarding the potential effect of ART on the nutritional needs of lactating women, particularly in resource-limited settings where breastfeeding is ubiquitous. ARVs affect nutritional status, body composition, breast growth, and lipid metabolism; however, the impact of ART on breast milk composition in HIV-positive lactating women is unknown.

- Further research is urgently needed to examine the potential impact of ART on the growth, development, and nutritional status of HIV-positive and negative children born to mothers living with HIV in regions characterized by extensive malnutrition and overlapping epidemics of HIV/AIDS and undernutrition.

CONCLUSION

Nutritional management and universal access to ART are essential weapons in the arsenal against HIV/AIDS. Nutritional management represents an important adjunct to ART, and may improve ART safety, efficacy, and adherence; reduce the impact of ARV side effects; alleviate the nutritional consequences of ART; and increase survival and quality of life. In the context of rapid scale-up of ART, comprehensive HIV/AIDS care and treatment programs including integrated nutritional management are of paramount importance.

Nutritional status coupled with dietary counseling should be considered by governments and external aid agencies involved in providing health services and evidence-based programmatic recommendations for people living with HIV. This would facilitate the rapid identification and resolution of nutritional problems and confer benefits such as improved nutritional status, improved health, and reduced disease progression in affected populations. However, ensuring access to ART should remain the top priority of these agencies, as treatment has the single largest beneficial effect on nutrition and survival in individuals with HIV/AIDS.

There is an urgent need for further research to inform optimal clinical and nutritional management of the HIV-positive individual. Areas in need of further study include: nutritional assessment, nutrition-ART interactions, safe and efficacious dosages of multivitamin supplementation (single-dose RDA vs. multiples of the RDA) to delay disease progression, nutritional composition of macronutrient supplementation, identification and development of palatable and locally available foods to improve nutritional status, and effects of ART on growth and development in HIV-positive children.

The overlapping pandemics of HIV/AIDS and undernutrition pose serious clinical and programmatic challenges to health-care providers in resource-limited settings. As access to ART is rapidly scaled up, commensurate increases in nutritional management are urgently needed to ensure the health and well-being of all those living with HIV.

HIV Postexposure Prophylaxis: General Recommendations and Lessons Learned from Jos University Teaching Hospital, Nigeria

Raphael Onu Ojoh,a John Idoko,b Bitrus Badung,c Patricia Agaba,a and Oche Agbajib

Jos University Teaching Hospital (JUTH) is situated in Jos, the capital city of Plateau State in the north-central region of Nigeria. It is a tertiary health facility serving a region comprising six states. Plateau State has an HIV prevalence rate of 6.3%, which is above the national rate of 4.4%. The antiretroviral therapy (ART) clinic at JUTH cares for about 12,000 patients living with HIV, representing one of the largest ART clinics in Nigeria. The hospital’s laboratory is equipped to perform HIV antibody screening, Western blot (for confirmatory testing), and tests for viral load, CD4 lymphocyte count, hematology, liver function, pancreatic amylase, electrolytes, and creatinine. The HIV postexposure prophylaxis (PEP) program has access to the same laboratory services used for HIV patient care. An infection prevention and control team at JUTH oversees the provision of PEP. Members of that team include a physician, laboratory scientist, nurse counselor, patient tracker (for patient follow-up), and pharmacist. The team is also responsible for the sensitization of hospital staff on safety measures to prevent exposures to HIV in the course of their work.

In an attempt to reduce the spread of HIV infection among health-care workers at JUTH, a committee was set up to oversee and manage cases of accidental occupational and non-occupational exposure that carried a risk of HIV infection. Over three years, we monitored health-care workers (occupational) and others (nonoccupational) who were exposed to the blood, tissue, or body fluids of patients who were HIV positive or of unknown status. Exposed individuals received risk assessment, counseling, HIV testing, and, if deemed appropriate, HIV PEP to prevent HIV infection.

The information presented in this chapter is based on lessons learned from the provision of PEP at JUTH, as well as general guidelines and recommendations for PEP in resource-limited settings. Although many of the recommendations in this chapter may be applicable to settings other than JUTH, it is important to modify approaches to PEP based on local conditions and the patient population being served.
DEFINITION OF POSTEXPOSURE PROPHYLAXIS

HIV PEP is drug therapy given to prevent HIV infection after direct contact with blood, tissue, or body fluids believed to be from an HIV-positive source. PEP is aimed at preventing HIV from invading sites of the human body known as “sanctuaries,” which include the lymph nodes and testes. Within the first 72 hours of HIV exposure, these sites are thought to be invaded by the virus, which remains there permanently. Therefore, administering HIV PEP within 72 hours of exposure to HIV is the most effective way of preventing HIV infection.

TYPES OF HIV EXPOSURE WARRANTING PEP

There are basically two types of exposure that may warrant PEP: occupational and nonoccupational.

**Occupational exposure** occurs when, in the course of his or her work, an individual is exposed to blood, tissue, or body fluids from an individual who is confirmed or believed to be HIV positive. This type of exposure is more common in hospitals and clinics but can occur anywhere as long as the exposed individual was performing work duties at the time of the incident.

**Nonoccupational** exposure, as the name implies, occurs outside the workplace and is not associated with the individual’s job. This type of exposure includes rape and sexual assault, condom breakage during sexual intercourse with an HIV-positive individual, and contact with HIV-contaminated blood or body fluids outside one’s place of work (e.g., at an accident scene).

Other instances of nonoccupational exposure include human bites, fights that involve the shedding of blood, and rituals and other practices that involve the exchange of blood and blood products. Practices such as scarification, female genital mutilation, and local surgeries in which equipment sterility cannot be guaranteed may also lead to nonoccupational exposure.

Nonoccupational exposure cases from rape and sexual assaults are commonplace and frequently go unreported because the survivor fears molestation and embarrassment from the public and relatives. Most referrals of rape cases are received from peripheral health facilities. Thus, it is important that health-care providers at all levels are fully aware of the availability of PEP services and the short response time required for effective treatment. Health-care workers should also be able to assess the patient’s risk of exposure according to the type of contact that has occurred. Sexual assault and rape are violent acts that can result in cuts and abrasions— Injuries increase one’s risk of exposure to HIV and should therefore be treated with the utmost seriousness. In addition to PEP, survivors of rape and sexual assault should be offered antibiotics to protect them from other sexually transmitted infections and should receive extensive psychological counseling.

CRITERIA FOR RECEIVING HIV PEP: DEFINITION OF LOW AND HIGH RISK

**Occupational Exposures**

The following occupational exposures are at high risk for HIV infection:

- Severe percutaneous deep injury (e.g., cut during amputation, piercing by bone speckle, deep penetrating injury during a medical procedure)
- Direct contact with a large amount of blood (e.g., blood splash)
- Visible blood of the source person on the invasive device
- Needle-stick injury from a needle that has been in contact with the source patient’s artery or vein
• Source patient known to be in the acute seroconversion stage or advanced stage of HIV disease

The following circumstances constitute a low risk for HIV infection:
• Contact with mucous membrane or nonintact skin
• Contact with a small amount of blood (i.e., a drop of blood)
• No blood from the source person visible on the invasive device
• An abrasion with no significant bleeding
• Source person with asymptomatic HIV infection and/or low viral load

When mucous membrane or nonintact skin is exposed to a large amount of blood (e.g., blood splashing into the eye), it is considered a high risk for HIV infection because of the quantity of blood involved and the susceptibility of the exposure site. Exposures to other body fluids, such as pleural, pericardial, peritoneal, and amniotic fluids, though they may lead to HIV infection, are termed low risk because they contain a lower viral count compared with that of blood or blood products. In all cases of potential exposure, the source blood or body fluid must be confirmed as being from an HIV-infected individual whenever possible.

The key issue in deciding whether a person should receive PEP is the determination of whether a potential exposure to the infectious material has occurred (see Tables 1 and 2). For potential exposure to occur, there has to be a break in the lining of the skin, as with a needle-stick injury, cuts by sharps contaminated with HIV-positive fluid, or a spill or splash of contaminated fluid over an open wound. A mere splash or spill of contaminated fluid over intact skin is not considered a potential exposure.

If the HIV status of the source patient is unknown or has not been verified by a trustworthy source, that patient will have to be screened for HIV antibodies after appropriate counseling to confirm his or her status. If the screening test is negative and the patient is not at high risk for HIV infection, the injury may be considered not a risk for HIV infection and therefore may not require HIV PEP, especially in a low-prevalence setting. However, in JUTH and many other settings in sub-Saharan Africa where there is a high prevalence of HIV, PEP may be considered even though the source patient is found to be negative for HIV antibodies.

Polymerase chain reaction (PCR) testing of the source person when available may be advised after a negative screening test if that person meets any of the following criteria:
• Child under 18 months of age born to an HIV-positive mother
• Recent history of unprotected sexual intercourse with a person of unknown HIV status (an earlier clinical history to elicit this is important)
• One of a discordant couple
• An indeterminate result from a Western blot test (PCR can be used as a tiebreaker)

Nonoccupational Postexposure Prophylaxis

In cases of potential nonoccupational exposure, risk should be assessed based on the HIV status of the source (if known) and the type of exposure. Figure 1 (next page) provides a basic algorithm for the assessment and management of nonoccupational exposure risk. As with all HIV PEP, the exposure must have occurred less than 72 hours from the initiation of treatment in order for non-occupational postexposure prophylaxis (nPEP) to be effective.

PROCEDURES FOR ADMINISTERING PEP

Administering PEP after a potential exposure is a relatively straightforward process. HIV screening of the exposed person is done within the first hour of presentation. If the exposed person is found to be HIV negative and it is determined that there is
The PEP officer will usually ask preliminary questions about the nature of injury to rule out “assumed injury.” Whenever possible, it is essential to verify whether the source person is HIV positive. Instances abound when PEP that was commenced outside the hospital had to be stopped because the source patient was confirmed to be HIV negative. Some health-care workers are not aware that PEP is given only when the source person is known to be HIV positive or of unknown status, regardless of the severity of the worker’s injury.

**Figure 1. Algorithm for evaluation and treatment of possible non-occupational HIV exposures**

Source: Smith DK et al.
CRITERIA FOR PROVISION OF PEP

The question of who should access PEP continues to be discussed in the medical community because of the serious consequences of seroconversion. The following guideline is based on the Nigerian national guidelines for administration of ARVs for both occupational and nonoccupational exposure.

For an individual to access HIV PEP, the following criteria must be met:

- Patient has been exposed to HIV-contaminated fluid, blood, or tissue within 72 hours of initiation of therapy.
- There is confirmation that actual exposure is highly likely to have occurred (i.e., patient has had low- or high-risk contact with blood, tissue, or other body fluids from source person known to be HIV positive or of unknown status).
- Exposed individual has been screened for HIV antibodies and found to be seronegative.

COUNSELING FOR HIV PEP

A brief counseling session takes place before the exposed person is sent for HIV screening. Counseling provides reassurance and is also needed to obtain consent for an HIV screening test. After screening, posttest counseling is provided, and the results are reviewed by the same doctor who prescribes ARVs. If the patient is found to be eligible for PEP, the physician and the pharmacist provide drug adherence counseling. Possible adverse effects
of the drugs and ways to manage them are also explained at this time. A dedicated phone number is given in case the patient has questions about side effects or other treatment issues, and HIV prevention counseling is provided. The patient is advised to abstain from unprotected sexual intercourse and blood donation during the treatment period.

**SELECTION OF ARV DRUGS FOR HIV PEP**

ART for HIV PEP consists of drugs known to be efficacious while producing minimal side effects. The goal is to give the most effective ART within the shortest time and with the least chance of adverse reactions. For HIV PEP, two or three drugs from one or two classes of ARVs are used. Two drugs from the same class are used for low-risk cases, while three drugs from two classes are used for high-risk cases. JUTH offers three ARVs when it cannot be determined whether the exposure was low or high risk. The most widely used drugs for PEP are zidovudine (AZT), lamivudine (3TC), indinavir (IDV), and lopinavir (formerly called ABT-378).

ARV selections are ideally based on whether exposure is deemed to be high or low risk. In high-risk situations, we offer two nucleoside reverse transcriptase inhibitors, usually AZT and 3TC (Combivir) and IDV/r (a ritonavir-boosted protease inhibitor). Nevirapine is avoided because of the risk of hypersensitive reactions, which are more common among patients with high CD4 counts (males >400 cells/mm$^3$ and females >250 cells/mm$^3$).

$^a$For skin exposures, follow-up is indicated only if evidence exists of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).

$^b$HIV positive (class 1): asymptomatic HIV infection or known low HIV RNA viral load (e.g., <1,500 copies/mL); HIV positive (class 2): symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load; unknown HIV status: for example, a deceased source person with no samples available for HIV testing; unknown source: for example, a needle from a sharps disposal container.

$^c$The recommendation “consider PEP” indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the doctor regarding the risks versus benefits of PEP.

$^d$If PEP is offered and administered, and the source is later determined to be HIV negative, PEP should be discontinued.

Source: Clinical Manual for Management of the HIV-Infected Adult.$^h$
The decision to prescribe ARVs for PEP is also based on whether the source patient (and/or the patient’s mother in the case of a pediatric source patient) is responding well to a particular ART regimen. For example, if the source patient has failed first-line therapy, the transmitted HIV strain may be drug resistant. This would necessitate elaborate investigation, including an HIV drug resistance test, to establish the most effective therapy. In the absence of these tests, the choice of drugs for PEP should be based in part on empiric HIV drug resistance data of first-line therapy failures. A complex case such as this, while possible, is a rare occurrence.

**EXPERIENCES FROM JUTH**

Accessing HIV PEP begins at the point of exposure. All the wards, theaters, and dressing/injection rooms in JUTH have notices on where and how to access PEP after exposure. Health-care workers have also received training on injection safety and universal precautions, and have attended a sensitization workshop on PEP. When a potential exposure occurs, the officer in charge of the unit is notified, and then the PEP officer is informed. The PEP officer has an open telephone number that is widely circulated to allow for unrestricted access. The hospital PEP team is headed by a physician assisted by a pharmacist. Other members of the team include a counselor and a laboratory scientist. This team is on call 24 hours a day, and all have one another’s phone numbers for ease of communication.

PEP drugs are always available for dispensing on instruction. The time to complete all needed steps varies from 15 to 20 minutes. However, universal precautions are usually undertaken even before notification (i.e., the site of injury is washed with clean running water using soap or liquid detergent). Because of panic, some health-care workers use bleach to wash their hands; this may not be necessary because clean water and soap are sufficient. When the conjunctiva is involved, the exposed person should use only clean water to irrigate the eyes; using soap on the eyes could increase the chances of infection and irritation.

We have found that it can be challenging to counsel health-care workers to receive HIV tests, the prerequisite for receiving HIV PEP. In some instances, health-care workers have refused HIV screening for fear of being diagnosed as HIV positive. This fear can often be allayed through reassurance that testing is voluntary and confidential. Exposed persons who refuse counseling and testing at the facility where they work are referred to another facility to receive the necessary intervention. In practice, it is difficult to deliver an HIV-positive result to a co-worker. Physicians are sometimes the most difficult cases; often they are willing to take PEP to prevent infection but do not want to be screened for HIV infection. Despite these difficulties, the policy at JUTH is that refusal to have HIV testing at baseline does not delay initiation of PEP. PEP is begun while the health-care worker receives further counseling on the need for the test, as PEP is usually not adequate to treat HIV infection if the HIV test is positive at baseline.

Challenges also arise when the source patient refuses HIV screening. In such cases, we proceed to manage the health-care worker or other potentially exposed individual as a case of high-risk exposure. It is also important to take a thorough history from the source patient to determine whether the risk of exposure is high and, if so, the anticipated window of opportunity. If the risk for recent exposure is high but the source person is found to be seronegative, a repeat screening test should be provided at a later date. In that case, the exposed person is still offered HIV PEP because of the high HIV prevalence in the JUTH setting.

Needle-stick injury occurring in the course of pediatric care when the mother is known to be HIV infected is followed by mandatory PCR on the
child if under 18 months of age, because an antibody test is not reliable for young infants (in settings that cannot offer PCR, the exposed individual should be offered PEP). For children older than 18 months, an antibody test should be done on the child after the parents receive counseling.

Preliminary investigations are usually done before commencement of PEP to establish a baseline for monitoring any abnormalities in organ functions caused by drug side effects. These include a liver function test (liver enzymes such as alanine and aspartate transaminases, total proteins, and alkaline phosphatase), serum urea and creatinine (for renal function), and pack cell volume or hemoglobin (for anemia and to possibly exclude the use of AZT). These investigations are repeated if the patient presents with symptoms suggesting an adverse reaction to the drugs. Patients are encouraged to report any side effects to the PEP team directly or to call a dedicated telephone line for further assistance.

CHALLENGES AND NEXT STEPS
Based on our experiences, some challenges related to the effective use of PEP include the following:

- Mandatory HIV screening prior to PEP initiation may not be widely acceptable.
- PEP is not 100% effective, so seroconversion could occur regardless of adherence to the PEP regimen.
- People who have been exposed to ARVs and subsequently seroconvert may develop resistance if the initial dose was suboptimal or if less than three ARV drugs were given.
- Not enough studies have been done on PEP in humans. PEP knowledge to date is largely based on animal studies.
- Follow-up for cases of HIV PEP is poor, and cases of rape and sexual assault are often reported very late, making ARVs less efficacious.
- JUTH is short staffed and therefore overburdened by this additional responsibility, particularly when patient follow-up is required. Creating a database to track patients receiving PEP could be helpful.
- We observed that poor communication was one of the problems associated with delivery of PEP services. Therefore, a dedicated telephone line was created to provide information about PEP and how to receive it.
- Drug stock-outs should be anticipated because the number of PEP cases cannot be accurately forecasted. We aim to stock three times the number of drugs we expect to use. For example, we see an average of eight cases every month, so we have 24 doses in stock. For centers that do not provide free ART, this might be a major constraint. Help from donors could be sought in these cases.
- There is general underreporting of exposure cases because of many factors, including lack of knowledge about the availability of PEP services. We are tackling this issue through sensitization workshops.

CONCLUSION
HIV PEP should be incorporated into all health-care facilities and coordinated by a team that responds to both nonoccupational and occupational exposures. There should be an enhanced public awareness campaign notifying the public and health-care workers alike about HIV PEP services and how to access them. Adequate resources, drugs, and staff should be provided at health facilities to care for individuals exposed to HIV. Improved HIV PEP data collation and interpretation will also help educate the medical community and the public on better ways of managing HIV exposure. Toward that end, the provision of PEP should be accompanied by routine data collection.
REFERENCE LIST

OPPORTUNISTIC INFECTIONS, CANCERS, AND COINFECTIONS
THE CENTRAL NERVOUS SYSTEM (CNS) is one body system significantly affected by HIV infection. In addition to the direct invasion of the CNS by HIV, which is a neurotrophic virus, the gradual deterioration in the host’s immune function indirectly leads to the colonization of the CNS by opportunistic infections (OIs).¹ The spectrum of CNS disorders ranges from mild self-limiting conditions to severe life-threatening infections and malignancies. There is significant overlap in the presentation (i.e., signs and symptoms) of HIV-associated CNS disorders.² To reduce the high morbidity and mortality associated with delayed or missed diagnosis of life-threatening CNS disorders, the clinician must have the capacity to make a prompt, accurate diagnosis and to initiate immediate therapeutic measures. Clinical skills, laboratory support and, where available, neuroimaging tools (e.g., computerized axial tomography [CAT] scans) are all helpful in achieving the best possible outcomes.

The clinician in resource-limited settings faces considerable challenges in promptly diagnosing and managing CNS disorders in people living with HIV. The high prevalence of HIV in parts of Africa and other resource-limited settings has led to a significant increase in the burden of CNS infections and malignancies.³ The limited expertise of clinicians in neurological assessment, coupled with the widespread lack of laboratory capacity for cerebrospinal fluid (CSF) analysis, may lead to unnecessary delays in the diagnosis of CNS disorders. CAT scans and magnetic resonance imaging (MRI) technologies, which are both key diagnostic tools for CNS disease, are rarely available, even at tertiary levels of care. These difficulties are compounded by the fact that in many instances, CNS disease may be the initial indication of HIV infection.⁴ Thus, there is a real need for more accessible and affordable diagnostic tools to support clinicians in the timely management of CNS disorders in resource-limited settings.

Decision rules, or algorithms, constructed from an understanding of the presentations of the most common diagnoses, are one such diagnostic support tool that clinicians in resource-limited settings may find useful.⁵ The algorithms are stepwise pathways that start with categories of diseases (by cause) based on readily available skills and tools (i.e., physical diagnosis and basic tests), followed by further subcategorization based on more specific laboratory investigations (e.g., CSF...
approach to the hIV-poSItIVe patIent wIth headache

The Etiology of Headaches in the Setting of HIV Infection

Headache is one of the most common complaints among HIV-positive patients in outpatient settings. Among HIV-negative individuals, headache is rarely due to significant intracranial pathology, even when patients present in an emergency setting. In the HIV-positive individual, however, the complaint of headache must always be taken seriously. In the setting of HIV infection, headache may indicate the presence of life-threatening infections that, if not promptly diagnosed and treated, can lead to death or severe disability. Causes of such fatal headaches include meningitis due to Cryptococcus neoformans, Mycobacterium tuberculosis, Streptococcus pneumoniae, and Toxoplasma gondii encephalitis. HIV-positive individuals also suffer from headaches with etiologies similar to those suffered by HIV-negative individuals, including sinusitis, aseptic meningitis, vascular headaches, and tension headaches. Drugs such as zidovudine (a commonly used antiretroviral agent) are also known to cause headache. The differential diagnosis of headache in the HIV-positive individual is therefore quite wide.

Algorithmic Approach to Differential Diagnosis

An algorithmic approach can be employed to support clinicians in resource-limited settings who are faced with HIV-positive individuals presenting with headache. The algorithm presented here (Figure 1) was constructed with the following assumptions in mind:

- Individuals presenting with headache are already known to be HIV-positive.
- The complaint of headache has been voluntarily brought to the attention of a health-care worker rather than being elicited.
- The algorithm is not exhaustive; rather, it is a tool that enables the diagnosis of the most common, and perhaps most life-threatening, conditions.

The recommendations in the following algorithm are based on an understanding of the common causes of headache in people living with HIV in ambulatory and inpatient facilities in resource-limited settings. The algorithm employs increasingly sophisticated methods to differentiate the etiologies of headache, starting with the most basic approaches (e.g., history taking, examination, basic tests), moving through to lab-based approaches (e.g., CSF examination and chest radiographs), and then to specialized tests (e.g., neuroradiological imaging, serum cryptococcal antigen [sCRAG] tests, and blood cultures). These three levels of sophistication mirror the capabilities commonly found in primary, secondary, and tertiary levels of care. What follows is a detailed description of the diagnostic process.
The Diagnostic Process

The HIV-positive individual who presents with headache should always undergo an initial clinical evaluation consisting of a detailed history, physical examination, and some basic tests (including malaria smear in malaria-endemic regions). This basic evaluation may immediately yield some readily identifiable causes of the headache, including sinusitis, migraines, dental carries, hypertension, malaria, and other infectious processes (e.g., typhoid fever, yellow fever).

Where such a cause is identified, appropriate therapy should be instituted. If there is no readily identifiable cause, the next step in the diagnostic process is to determine whether there are focal neurological symptoms and signs associated with the headache. These include weakness of one side of the body (hemiplegia/hemiparesis), cranial nerve deficits, unstable gait (ataxia), speech disorder (aphasia), and convulsions (seizures). If an HIV-positive individual presents with a headache associated with focal neurological findings, empiric treatment for toxoplasma encephalitis (TE) should be initiated immediately. Because the presence of TE, which is a treatable diagnosis, represents an important opportunity to reverse neurological deficits, TE
should always be considered in patients with focal findings. Seven days after the empiric trial of therapy, the patient should be evaluated for a response. Reduction of weakness should warrant completion of antitoxoplasma therapy for at least six weeks. If after seven days the weakness does not significantly change or worsens, further diagnostic workup is warranted.

If the individual has no readily identifiable cause for the headache (on the initial basic evaluation) and has no focal neurological findings, the clinician should determine whether any of the following are present:
- Altered state of consciousness (confusion, stupor, or coma)
- Neck stiffness
- Hypotension

If any are present, an immediate lumbar puncture (LP) for CSF analysis, followed by empiric broad-spectrum antibiotics (given intravenously to cover bacterial meningitis), should be performed. If a CSF examination is not possible, empiric broad-spectrum antibiotics should be given immediately, and the patient should be referred, if possible, to a center where CSF analysis can be done. The choice of antibiotics should be informed by the local sensitivity patterns of the common isolates of bacterial organisms that cause meningitis and bacteremia in HIV-infected individuals.

Following CSF analysis, a number of diagnoses may become apparent, including the following:
- Cryptococcal meningitis (CM)
- Acute bacterial meningitis
- Aseptic (viral) meningitis
- Tuberculous meningitis
- Neurosyphilis/syphilitic meningitis

If any of these meningitides are diagnosed, the appropriate antimicrobial therapy should be instituted. (The management of CM is described in more detail later in this chapter.)

The CSF analysis may not reveal a specific diagnosis in individuals who do not have any focal findings. These individuals should be reassessed 48 hours after the initial assessment. For those who show improvement in their general conditions, further clinical observation should be done with symptomatic management. The clinician should consider performing one or more of the following when he or she follows up with individuals who experience either no improvement or a worsening of their condition:
- Repeat LP with CSF culture
- Blood cultures for fungal and mycobacterial isolation
- Chest X-ray
- Empiric antifungal and/or antimycobacterial therapy

If no further insight or improvement occurs after instituting the above measures, additional diagnostic workup is warranted (see below).

The clinician may be faced with a situation in which the patient without focal findings does not have any of the findings that require immediate LP (Figure 1). Such individuals should be managed symptomatically with analgesics and reassessed within 48 hours for progress. Individuals with improved symptoms should be observed further until they are fully well.

If no improvement occurs or if the symptoms worsen, an LP with CSF exam is recommended. Further management depends on the CSF findings, with any isolated organism being treated with appropriate antimicrobials. Further diagnostic workup is warranted for those individuals without any positive findings on CSF examination.

**Further Diagnostic Workup**

As noted previously, three instances warrant further diagnostic workup. The individual under investigation will need to undergo tests that may
only be available at a tertiary care facility, requiring referral to such a facility. The following tests are suggested at this stage to facilitate a more accurate diagnosis:

- CD4 lymphocyte count: Counts below 200 cells/mm³ are strongly suggestive of an OI.
- CAT scan: Can demonstrate structural lesions of varied etiology.
- Serum/CSF CRAG: Will aid diagnosis when India ink is negative (20% of cases) and when the CSF culture for *Cryptococcus neoformans* may take a while to grow yeast cells.

**MANAGEMENT OF SELECTED CNS DISORDERS THAT PRESENT WITH HEADACHE**

**Cryptococcal Meningitis**

CM is the most common life-threatening fungal infection among people living with HIV globally and is now the leading cause of meningitis among adults in areas of high HIV prevalence.¹ The causative organism, *Cryptococcus neoformans*, is a capsulated fungus that is commonly isolated from pigeon droppings and is widely distributed in soils. The infection is acquired via the lungs through inhalation of aerosolized organisms, which then establish a pneumonitis in the lungs followed by dissemination throughout the body in immunocompromised individuals. The organism has a predilection for the CNS; in a setting of profound immunosuppression resulting from HIV infection, this organism can lead to fungal meningitis.¹²

The onset of symptoms due to CM is insidious, with headache being by far the most common symptom. The headache is usually reported as frontal in location and occasionally as radiating to the occipital (back) region of the head. If the condition is not treated, the initially mild headache will gradually become severe and incapacitating. The headache may be associated with sixth-cranial-nerve palsies (an indicator of raised intracranial pressure) and changes in mental state. HIV-positive CM patients do not commonly report seizures. Compared with HIV-seronegative individuals with CM, up to 50% of HIV-associated CM patients may not have symptoms and signs of meningeal irritation (e.g., neck stiffness, positive Kernig’s sign).¹³ The non-specific presentation of CM in HIV-positive individuals requires that clinicians have a high index of suspicion to readily diagnose the condition and significantly reduce the high mortality associated with it.

The diagnosis of CM is established by examining CSF using India ink stain (through demonstration of a thick capsule around the fungal organism) or fungal cultures for the causative organisms using Sabouraud’s agar. Screening for CM among symptomatic individuals is best done with an sCRAG test, an agglutination assay that requires limited laboratory infrastructure. The sCRAG assay has a very high positive predictive value (99%) for CM in symptomatic individuals (i.e., those with headache).¹⁴

In summary, HIV-positive individuals with headache—particularly those in high-prevalence areas—have a very high likelihood of developing CM. Despite the high positive predictive value of the sCRAG test, patients with a positive result should nevertheless undergo LP for several reasons. First, LP offers the opportunity for a definitive CM diagnosis through CSF analysis. Second, LP in CM patients with raised intracranial pressure (ICP) offers some therapeutic benefit by relieving the pressure through CSF drainage. Finally, in some instances, HIV-positive individuals may have multiple CNS infections; the only way to detect this is by analyzing the CSF.

Management of CM consists of the following steps:
1. Initiation of specific antifungal therapy

Antifungal therapy occurs in three phases. Table 1 lists both the preferred and the alternative treatment regimens.15

2. Management of raised ICP

CM in people living with HIV is very often associated with elevated ICP; this is particularly true in resource-limited settings, where patients presenting at a health facility may be at a late stage of disease. Because of the association of raised ICP with high mortality, the Infectious Diseases Society of America (IDSA) guidelines for the management of HIV-associated CM recommend the management of raised ICP as an integral part of CM management.15 ICP management is achieved through serial drainage of CSF directly from the diagnostic LP. In settings where CSF manometers (for measurement of CSF pressure) are not readily available, it is advisable to perform generous drainage of CSF (>10 mL) in patients with focal neurological deficits. The safety of this procedure has been demonstrated in a small study in Uganda among HIV-positive patients with CM.16

3. Exclusion of concurrent OIs

The high mortality observed in CM patients may partly result from concurrent OIs. For example, one study found that as many as 27% of patients with HIV-associated CM also had active tuberculosis.17 Therefore, active screening for common OIs is recommended in CM patients.

4. Initiation of antiretroviral therapy

CM occurs in severely immunosuppressed individuals, and a CM diagnosis implies advanced HIV disease (World Health Organization [WHO] stage IV). Following the management of the acute episode of CM, it is imperative that patients be prepared for and initiated on antiretroviral therapy (ART). However, very early ART initiation may be associated with immune reconstitution inflammatory syndrome (IRIS; see section later in this chapter).

**Toxoplasma Encephalitis**

TE is the most common cause of focal neurological deficits among HIV-infected individuals.18 TE is caused by *Toxoplasma gondii*, a highly prevalent parasitic infection of the brain that is usually latent but is reactive in immunosuppression settings. The reactivated infection leads to clinically apparent disease.19

The common presentations of TE include hemiparesis or hemiplegia, unilateral facial weakness (i.e., cranial nerve lesions), ataxia, and seizures, as well as aphasia, depending on the part of the CNS affected. The onset of symptoms is usually insidious rather than sudden, even though TE

lesions involving the cerebral vasculature can lead to sudden presentation.20

The diagnosis of TE is initially made on clinical grounds (i.e., focal neurological deficit in a setting of profound immunosuppression) and is augmented by serological evidence of active Toxoplasma gondii infection (i.e., elevated serum antitoxoplasma IgG titers). Definitive diagnosis is made using neuroradiological imaging. Typically, the contrasted CAT scan shows ring-enhancing lesions that may be multiple and that are usually in the area of the basal ganglia. In settings without access to CAT scan technology, diagnosis can be made when the patient responds to antitoxoplasma therapy (Table 2).21

Because the diagnosis of TE in resource-limited settings is usually presumptive (i.e., based on the clinical presentation), patient response to antitoxoplasma therapy is essential for confirming the presence of TE. Patients are assessed after two weeks of empiric antitoxoplasma therapy, and responsive individuals continue the treatment regimen as indicated. Individuals with minimal or no improvement should undergo evaluation for other HIV-associated conditions that present with features similar to TE, including primary CNS lymphoma (PCNSL), progressive multifocal leukoencephalopathy (PML), and meningovascular syphilis.22

PCNSL is a neoplasm of B-cell origin that affects HIV-infected individuals who have advanced immunosuppression. The Epstein-Barr virus (EBV) has been implicated as a cause for PCNSL. Patients with PCNSL present with focal neurological findings, including weakness on one side of the body, facial weakness, or speech defects, depending

</table>
of the part of the brain affected. Diagnosis is aided by CAT scan imaging, which usually shows a solitary, deep (subcortical) brain lesion that minimally enhances on contrast. These features may help distinguish PCNSL from toxoplasmosis, particularly if the patient does not respond to empiric antitoxoplasma therapy within two weeks. Treatment of PCNSL consists of radiotherapy and chemotherapy, either singly or combined. Even with treatment, however, median survival ranges from two to four months.

PML, an OI that affects the brain, is caused by the John Cunningham virus (JCV; a human polyomavirus). Like PCNSL, PML presents with focal neurological symptoms and signs in advanced HIV disease; it is easy to distinguish PML from PCNSL and TE with neuroimaging. Lesions seen on a CAT scan are usually limited to the white-matter portion of the brain and are not ring enhancing on contrast. There is no known effective treatment for PML, though in a few individuals, use of cytosine has resulted in some improvement. There have also been some documented cases of spontaneous remission.

Meningovascular syphilis usually occurs in early HIV disease and, in this regard, is relatively easy to distinguish from PML, TE, and PCNSL.

**Immune Reconstitution Inflammatory Syndrome**

Between December 2003 and June 2006, the estimated number of individuals receiving ART in low- and middle-income countries increased fourfold. This increase has led to tremendous reductions in morbidity and mortality from HIV-associated OIs. Unfortunately, this restoration of immune function can also lead to an abnormally heightened response to antigens in some patients, resulting in a clinical presentation characterized by inflammatory symptoms and signs. This situation is referred to as the immune reconstitution inflammatory syndrome (IRIS).

The manifestations of IRIS are diverse, depending on the body system affected. The scope of presentations includes meningeal symptoms, abscesses, fevers, cutaneous lesions, and chest symptoms, as well as hepatic liver enzyme abnormalities. In the CNS, IRIS may present as a meningeal syndrome, headache, or space-occupying lesion. The prevalence of IRIS in resource-limited settings ranges from 10% to 25% among individuals initiating ART. The most common antigens associated with IRIS in these settings are *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, and herpes simplex virus; however, IRIS has also been described for most opportunistic pathogens.

Most IRIS episodes are self-limiting, and only rarely is the syndrome life threatening. Unfortunately, the CNS is one system in which IRIS events can be fatal, because IRIS in the CNS may be associated with raised ICP as a result of inflammation. In CNS IRIS due to *Cryptococcus neoformans*, fungal CSF cultures are usually negative, despite the presence of cryptococcal antigen. The diagnosis of other CNS antigens that cause IRIS can be difficult in resource-limited settings due to limited laboratory capacity for mycobacterial and viral culture, including polymerase chain reaction (PCR) assays. Where CNS IRIS is associated with raised ICP, LP and drainage of CSF are recommended as part of the patient’s management. A further discussion of IRIS can be found elsewhere in this text.

**Approach to the HIV-Positive Patient with Visual Loss**

Visual loss and ocular diseases are a common complication among people living with HIV worldwide. In North America and Europe, it is estimated that 50% to 75% of HIV-positive individuals develop visual loss at some point during the course of their illness. In Africa, the prevalence of ocular disease...
among HIV-positive individuals is estimated to be between 30% and 45%. Visual loss is important because it can be the first manifestation of a life-threatening systemic disease process in the person living with HIV. The ocular diseases that cause vision loss result in irreversible blindness if not treated promptly and effectively.

The three main mechanisms that result in ocular manifestations of HIV and visual loss are as follows:

1. The depressed immunity in patients with advanced HIV disease predisposes them to OIs and malignancies that affect the eye.
2. Ocular allergic and toxic drug reactions are a complication of some of the medications used for treatment of OIs or the virus itself.
3. The HIV virus can have a direct effect on ocular tissues.

The pattern of ocular diseases affecting HIV patients in the African region, however, is different from that found in developed countries. Ocular tumors and OIs due to organisms such as *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, and *Toxoplasma gondii* are more frequent causes of ocular morbidity and visual loss in Africa, but in developed countries, cytomegalovirus (CMV) retinitis and immune recovery uveitis remain the leading causes of visual loss.

In the following section we review some of the common causes of visual loss seen in developing countries and the approach to patients presenting with these conditions.

**OPPORTUNISTIC INFECTIONS AND MALIGNANCIES**

Opportunistic ocular and systemic infections are the most common causes of visual impairment in people living with HIV/AIDS worldwide. These commonly occur in advanced stages of the disease when the patient’s CD4 T cell count falls below 100 cells/mm³.

**CMV Retinitis**

CMV is the number one cause of ocular morbidity and visual loss in HIV-positive individuals. The prevalence of CMV retinopathy in people living with HIV in developed countries before the introduction of combination ART was about 30% to 50%. It is documented that the prevalence of CMV retinitis is decreasing to 7.5% with the advent of ART in developed countries.

The prevalence of CMV retinitis reported in different African centers, however, is 0% to 8.5%. The mean CD4 T cell count at the time of CMV diagnosis is typically less than 50 cells/mm³, and diagnosis is rare with CD4 T cell counts greater than 200 cells/mm³. CMV retinitis was reported to be lower in Africa because of lack of effective treatment of OIs and ART; therefore, few patients survive long enough to develop CD4 T cell counts of less than 50 cells/mm³. However, more recent studies in Africa are documenting an increasing number of patients presenting with CMV retinitis over the past six years as ART is becoming more readily available.

Visual loss or blindness is the most common presenting symptom for CMV retinitis in developing nations like Africa because of late presentation and lack of routine ophthalmologic examinations of those at risk, which are a constraint due to limited resources.

In the early stages of retinitis, when lesions start away from the macula, patients may be totally asymptomatic or may have symptoms of floaters due to a vitreous reaction. Such patients can only be diagnosed by routine dilated fundoscopy. It is only in the advanced stages of the disease when a large area of the retina or the macula is affected that patients present with varying degrees of visual loss in the affected eye.

Diagnosis of CMV retinitis is largely made by the clinical appearance of the retinitis on ophthalmic evaluation with the supporting low CD4 T cell count.
levels. Serum antibody titers are not helpful; there is a 50% to 90% prevalence of seropositivity in the general adult population, and there is no relationship between antibody titers and the development of CMV retinopathy in people living with HIV.41

Table 3 summarizes the different diagnostic options that are used in different centers, depending on the resources available.

CMV retinitis responds to antiviral drugs such as ganciclovir, foscarnet, cidofovir, and valganciclovir.42-44 These drugs do not eradicate the virus from the eye. Patients therefore must receive chronic low-dose (“maintenance”) therapy to prevent the immediate reactivation of the disease. Recent studies also show that ART improves the patient’s immune system enough to control CMV retinitis.

Antiviral drugs for CMV retinitis are expensive and hardly available in developing countries. In such resource-limited settings, weekly intravitreal injections of ganciclovir or foscarnet are given to individual affected eyes together with ART until the patient’s CD4 T cell count improves to 200 cells/mm³ or more. This does not treat systemic CMV infection. In resource-limited settings, a typical fundus lesion, a supporting low CD4 T cell count, and a positive response to anti-CMV treatment and ART are the major parameters used to support diagnosis of CMV retinitis.

**Herpes Zoster**

Herpes zoster ophthalmicus (HZO) is a dermatome skin eruption along the distribution of the ophthalmic branch of the trigeminal nerve due to varicella-zoster virus. It may occur at any stage of the HIV infection but is often the first sign of the disease. Studies done in Africa reveal the prevalence of HZO in HIV-positive individuals to be 5% to 10%.45 Visual impairment occurs when there is an associated keratitis, anterior uveitis, or viral infection of the retina (progressive outer retinal necrosis [PORN]). Sixty-five percent of patients with HZO develop corneal complications and will become visually impaired.46 No data are currently available on the prevalence of PORN in the developing world. It has been reported in African patients, and risk factors include a low CD4 T cell count (less than 50 cells/mm³) and a recent or current cerebral or visceral herpes zoster infection.47

The associated clinical symptoms of cornea and anterior segment involvement include pain, redness, photophobia, and tearing. PORN presents as sudden, painless loss of vision in the affected eye. Diagnosis is made on clinical grounds. Patients with HIV infection and HZO should be treated with systemic acyclovir to promote healing of skin lesions and to reduce the incidence and severity of ocular lesions.

Antibiotic cover for secondary infection is usually required. HZO is another common cause of visual loss in developing countries because of poor referral systems to ophthalmologists. Traditional eye medicines are often applied to treat pain associated with the different stages of the disease, and these contribute to secondary infection, corneal ulcers, scars, and, many times, endophthalmitis.

**Herpes Simplex Virus**

Herpes simplex virus type 1 is a common cause of prolonged visual impairment in patients living with HIV.48 Vision-impairing lesions are a result of corneal involvement, anterior uveitis, and retinal infection. The keratitis is associated with pain and redness of the affected eye, and the retinal infection is painless with occasional floaters. Diagnosis is usually made on clinical grounds by identifying the characteristic dendritic or geographic corneal ulcers or disciform keratitis on slit lamp examination. Herpes simplex virus infection of the retina occurs in HIV-positive patients, causing acute retinal necrosis and PORN. Corneal lesions respond to topical antiviral therapy, but recrudescence may

People living with HIV are at risk for serious, disseminated *Toxoplasma gondii* infections, including toxoplasmic retinochoroiditis. This commonly occurs when a patient's CD4 T cell count falls below 100 cells/mm³. Visual impairment occurs as a result of reactivation of the infection within the retina or in the CNS. Zumla et al. found the seroprevalence for toxoplasma among people in Uganda and Zambia to be 34% among those who were HIV positive and 27% in those who were HIV negative. For reasons that are unclear, ocular toxoplasmosis is much less common than intracranial lesions. In developed countries, toxoplasmosis probably accounts for only 1% to 3% of all intraocular infections in HIV-positive patients.

Patients with ocular toxoplasmosis experience progressive and painless loss of vision. The retinitis can present as a focal necrotizing retinitis with an overlying vitreous reaction or with diffuse or multifocal lesions with minimal vitreous reaction. Such variations in presentation make diagnosis very challenging, especially in resource-limited settings. Those with intracranial lesions may report double vision and a squint, with reduced visual field due to involvement of cranial nerves or the visual pathway.

Diagnosis is made by ophthalmologic examination and positive antibody titers. CAT scan is necessary for suspected intracranial involvement. Lesions will respond to antiparasitic therapy consisting of pyrimethamine, sulfadiazine, and folic acid. Clindamycin, tetracycline, and spiramycin are also effective, but continued treatment is
necessary to prevent reactivation of disease. A positive response to therapeutic trial with a conventional combination of antibiotics is used to support diagnosis in resource-limited settings.

**Ocular Syphilis and TB**

Many patients living with HIV are also at high risk for syphilis because it is a sexually transmitted infection. Vision-impairing disease manifests as a prolonged uveitis, optic neuritis, or interstitial keratitis. Several epidemiological surveys show a high prevalence of active syphilis among HIV-positive patients in sub-Saharan Africa; however, there is no published information on the prevalence or clinical presentation of ocular syphilis in HIV-positive individuals in sub-Saharan Africa. A 1% prevalence of syphilitic uveitis has been reported in HIV-positive patients in Brazil. It is possible that complications leading to blindness attributable to syphilis do occur in developing countries but are probably underdiagnosed.

Diagnosis requires a positive plasma reagin test (VDRL or rapid plasma reagin) and a T. pallidum hemagglutination test (TPHA). Both tests are important in diagnosis and follow-up to monitor response to treatment. They are readily available in resource-limited settings. Treatment for ocular syphilis in HIV-positive patients requires the regimen used for neurosyphilis regardless of the CNS examination. This consists of intravenous penicillin or oral doxycycline. A decline in the VDRL titer to 1:4 occurs within six months. Long-term therapy may be required in some patients.

**Mycobacterium tuberculosis** can infect most tissues of the eye and is a well-known cause of uveitis in HIV patients. The most common form of ocular tuberculosis is a multifocal chorioidopathy. There are no features that are pathognomonic for tuberculosis, and lesions must be differentiated from other mycobacterial infections, *Pneumocystis carinii* infection, syphilis, and lymphoma. Choroidal infections can be complicated by scleral extension, serous retinal detachment, and a severe secondary granulomatous anterior uveitis. Response to anti-TB treatment supports diagnosis, but steroids are usually required to control inflammation.

**Neurophthalmic Disease and Ocular Tumors**

**Cryptococcal Meningitis**

Cryptococcal meningitis is a common complication in people living with HIV. Forty percent of patients with cryptococcal meningitis develop vision-impairing complications such as papilledema, optic atrophy, extraocular muscle paresis, and cortical blindness. Decreased vision has also been reported as the result of chiasmal or optic tract involvement and intraocular infections causing endophthalmitis, uveitis, and chorioretinitis. It is estimated that 8% to 10% of people living with HIV in developed countries develop multifocal choroidal lesions that result from *Pneumocystis carinii* and *Cryptococcus neoformans*. Other forms of meningitis such as bacterial meningitis do occur and would cause similar vision-impairing complications.

**Other Neurophthalmic Diseases**

A variety of other neurophthalmic abnormalities in people living with HIV may present as cranial nerve palsies, visual field defects, pupillary abnormalities, optic atrophy, and papilledema. They are commonly caused by disseminated intracranial infections, as mentioned above, or tumors that result in space-occupying lesions. Burkitt’s lymphoma may develop in the orbit of HIV-positive individuals. Proptosis, lid swelling, or ocular motility disturbances can be the first manifestation.

**Carcinoma**

Conjunctival squamous cell carcinoma and carcinoma in situ have a strong association with HIV infection. Studies show a prevalence of 70% to 86% seropositivity among African patients with
Squamous cell carcinoma can affect the eyelids, conjunctiva, or orbit. Early excision of this tumor is curative. Vision is lost in advanced stages when the tumor infiltrates the eyeball. This is a common finding in resource-limited settings, mainly because of lack of awareness at HIV treatment sites about the presentation of this tumor and late referral to an ophthalmologist.

**Sarcoma**

Kaposi’s sarcoma (KS) is a vascular tumor also commonly associated with AIDS. In the pre-ART era, ocular adnexal KS was found in 2% of patients with AIDS. It rarely causes visual loss when the tumor is large enough to cross the visual axis. The incidence of KS has declined in the ART era.

**DIRECT EFFECT OF HIV**

HIV has been recovered from most ocular tissues, including the retina and cornea. It has been proposed as the possible cause of the conjunctival microvasculopathy, cotton-wool spots, and retinal hemorrhages commonly seen in HIV patients. These are, however, asymptomatic and do not cause visual loss.

HIV is also believed to cause nonspecific intraocular inflammation and serve as a contributing factor in the pathogenesis of secondary disorders in some patients. This presents as a chronic iridocyclitis that cannot be attributed to any secondary intraocular infection or systemic inflammatory disease. The iridocyclitis resolves rapidly in some patients with ART (e.g., zidovudine), suggesting a direct relationship to HIV. Alternatively, inflammation might be the result of an unidentified infectious agent of low virulence that is successfully suppressed with improvement in the patient’s immune function.

The virus also acts as a cofactor in CMV retinopathy. Both viruses have been found in the same retinal cells at autopsy. Interactions between the two viruses, which are known to occur in vitro, may enhance the activity of CMV in coinfected cells and may be one reason that CMV retinopathy is more severe in some patients.

**OCULAR ALLERGIES AND TOXIC DRUG REACTIONS**

People living with HIV are usually on numerous medications for treatment of OIs and the virus itself. This predisposes them to drug toxicity and hypersensitivity reactions. When the eye is affected, it results in impaired vision and sometimes blindness. Stevens-Johnson syndrome is a blinding hypersensitivity reaction common to sulfur-containing antibiotics such as Septrin, antimalarials such as sulfadoxine/pyrimethamine (Fansidar), and thiacetazone in HIV-positive individuals. It causes an aggressive mucocutaneous inflammation, which causes the conjunctiva to adhere to the cornea, a condition referred to as symblepharon. One study done in Malawi showed 75% of patients admitted with Stevens-Johnson syndrome were HIV positive. Many of these patients were taking pyrimethamine. Other drugs associated with Stevens-Johnson syndrome in HIV-positive patients include phenytoin and nvrapine.

Ethambutol causes optic neuritis that can result in irreversible blindness if the drug is not withdrawn early. Cidovir, used to treat CMV retinitis, and rifabutin have been reported to cause severe vision-threatening uveitis. These are more commonly used in developed countries.

Immune recovery uveitis has also been reported in 18% to 63% of patients with a history of CMV retinitis who experience immune reconstitution while on ART. Drug toxicity and hypersensitivity reactions are managed by withdrawal of the offending drug and treatment with steroids.
A DIAGNOSTIC APPROACH TO THE PATIENT WITH LOSS OF VISION

Essential steps in examining the HIV-positive patient with impaired vision are presented in Figure 2 and include the following:

1. **History related to visual impairment.** A detailed history of the patient’s complaints should be taken. The mode of onset, duration, and description of his or her visual impairment will be noted. Any associated symptoms such as pain, redness, or double vision should be noted.

2. **Medical history related to visual impairment.** A history of past or current systemic illnesses that could cause visual impairment should be elicited. These include conditions such as diabetes mellitus, hypertension, rheumatoid arthritis, tuberculosis, and syphilis among many others. The patient’s past and current medication should be elicited to rule out the use of drugs that are toxic to the structures of the eye and can cause visual impairment.

3. **HIV-related history.** The patient’s past and present CD4 lymphocyte count should be determined. Most of the ocular diseases are diagnosed clinically, and a low CD4 count supports the diagnosis. The duration of use of antiretroviral drugs should be noted. The patient’s history of OIs and their treatment should be elicited such as tuberculosis, cryptococcal meningitis, toxoplasmosis, and so forth.

4. **Ophthalmic examination.** A complete ocular examination to determine the presence of eye disease should be carried out. It involves documentation of visual acuity and visual field testing. All patients should be refracted to rule out the presence of refractive error as the cause of reduced vision. Eyeball movements are tested in all directions of gaze. Pupillary function is also assessed. A slit lamp examination to view the structures in the anterior and posterior segment of the eye should be performed. Direct and indirect ophthalmoscopes are used to assess the fundus.

5. **Investigations.** Photography of clinical findings, visual field plotting, and CAT scan are done where indicated. Appropriate laboratory investigations to confirm diagnosis are performed. Table 2 summarizes diagnosis of some of the common causes of visual loss in the patient living with HIV.
# REFERENCE LIST

Kaposi’s Sarcoma (KS) is an AIDS-defining cancer that occurs with advanced immunosuppression associated with HIV. The causative underlying viral infection is human herpesvirus type 8 (HHV-8), also known as Kaposi’s sarcoma-associated herpesvirus (KSHV).1 Long before the AIDS pandemic, KS existed in the Mediterranean and Central Africa and in organ transplant recipients. Patients coinfected with both HIV and KSHV infection are 10,000 times more likely to develop KS compared with HIV-uninfected persons, and 50% of coinfected patients will develop a KS tumor within 10 years of HIV infection.2 The increased risk in HIV-infected patients is caused by immunosuppression associated with lowering CD4 counts. HIV-1 replication produces transactivating (tat) protein from the virally infected cells. The tat protein has pro-angiogenic (blood vessel proliferating) properties and with the aid of cytokines, sets the stage for the development of KS lesions.3 These factors, in conjunction with HHV-8 infection, cause proliferation of vascular lesions on the skin and viscera.

**CLINICAL PRESENTATION**

HIV-associated KS most commonly involves the skin, gastrointestinal tract, respiratory tract, and lymph nodes. Although cutaneous lesions are a source of much disfigurement and stigmatization, they are not associated with mortality; however, visceral lesions involving the respiratory or gastrointestinal tract are associated with mortality.4 KS presentation also varies depending on age, with adults usually presenting with cutaneous involvement and children typically presenting with the lymphadenopathic form of the disease.5

The lesions of Kaposi’s sarcoma are distinctively characteristic. They are violet-colored plaques directed along the cleavage lines of the skin and are usually symmetrical (Plate 1). They can occur at all sites: face, upper limbs, trunk, and lower limbs. However, many conditions can mimic these lesions; these are described in Box 1 (next page). The limbs are often the first sites to be involved (Plate 2). There they can present with nonpitting edema, which signifies lymphedema. Early-stage lesions can present as bruises or macules, which are merely discolorations of the skin (Plate 1), progressing to elevated, solid, violet-colored plaques and nodules (Plate 3). The lesions are asymptomatic and may go unnoticed by both patient and caregiver; identification is particularly difficult in dark-skinned individuals. Thus, thorough examination

Department of Dermatology, Nelson R. Mandela School of Medicine, University of KwaZulu-Natal, South Africa
in adequate light is essential. As the lymphedema progresses, it is associated with extreme pain.

Late-stage aggressive lesions may progress to fungating tumors (Plates 4 and 5). Because of the vascular nature of the tumors, lesions are prone to bleeding, which may be the primary cause for concern in the patient presenting for care. Regression of KS lesions is characterized by decrease in size (i.e., flattening and shrinking), usually accompanied by residual hyperpigmentation, even when lesions have disappeared. In some cases, plaques and nodules may disappear completely.

Oral involvement is commonly associated with cutaneous lesions and may occur in the absence of skin lesions (Plate 6). These appear as violet-colored macules, plaques, and nodules on the hard palate, gingiva, and tongue. The mouth may be the presenting site in approximately 20% of patients, and lesions there may herald a more rapidly progressive form of the disease with higher mortality than disease confined to the skin. They may also be a marker of pulmonary involvement.

Other commonly involved sites are the gastrointestinal tract, lungs, and lymph nodes. Lesions similar to those on the skin can be identified in all segments of the bowel and respiratory tree and can cause symptomatic gastrointestinal and respiratory disease. Bowel involvement will present as obstruction or blood loss, while respiratory involvement will present as cough and dyspnea (labored respiration), with or without fever and occasionally with hemoptyis (expectoration of blood from the respiratory tract). Systemic gastrointestinal and pulmonary involvement may occur in the absence of skin lesions. Gastrointestinal bleeding requires confirmation with a fecal occult blood test, but only endoscopy allows for an accurate diagnosis. If the patient presents with chest symptoms, sputa to exclude an infectious etiology and a chest X-ray are the first steps to identifying pulmonary KS. Suggestive findings on the chest X-ray are mediastinal enlargement and diffuse reticulonodular shadowing, and occasionally effusions. A definitive diagnosis requires bronchoscopy.

**DIAGNOSIS OF KS**

The approach to examination and investigation of a patient with KS is outlined in Box 2.

If a patient has an abnormal chest X-ray, sputa microscopy and culture are mandatory to exclude tuberculosis and *Pneumocystis carinii* pneumonia (PCP). If the patient has an effusion, a pleural tap is essential to exclude infective causes like tuberculosis. A hemorrhagic effusion is suggestive of KS. If the chest X-ray is abnormal, the patient has been treated empirically for a chest infection, and sputa are negative, a bronchoscopy should be considered. If the patient complains of passing blood from the rectum or has abdominal symptoms or melena stools, endoscopy and/or colonoscopy is necessary.
The importance of assessment for other opportunistic infections cannot be overemphasized, because Kaposi’s sarcoma is AIDS defining and patients presenting with KS suffer marked immunosuppression. Another reason assessing for opportunistic infections is essential is that they may cause progression of KS by way of proinflammatory cytokines. Corticosteroids have also been known to exacerbate KS lesions and should be avoided in patients with HIV KS. A good history of all current drugs is vital, especially antituberculous and antiretroviral medications. It will influence planning of therapies, especially when current chronic medication might interact with chemotherapy.

ANTIRETROVIRAL THERAPY AND KS

Because Kaposi’s sarcoma is an AIDS-defining condition associated with advanced immunosuppression, all HIV-infected patients require antiretroviral drugs (ARVs). ARVs have been shown to decrease the incidence of new KS cases among HIV patients and are associated with the resolution of KS lesions. The ability of ARVs to cause regression is thought to be linked to reduction in HIV-1 viral load and hence the HIV transactivating gene (tat), induction of spindle cell growth, improved immune response to HHV-8, and the direct antiangiogenic activity of some protease inhibitors (PIs). Thus, the basic workup for initiation of ARVs is the starting point for any patient with HIV KS.

Although ARV regimens differ from country to country, any potent regimen that leads to CD4 restoration and HIV viral load suppression will suffice. A review of antiretroviral therapy (ART) in advanced HIV infection found that non-nucleoside reverse transcriptase inhibitor (NNRTI) regimens achieved a higher rate of durable viral suppression compared with nonboosted PIs. Whether a regimen containing PIs is superior to an NNRTI-based regimen in HIV KS is unknown. A response rate of 20% was reported in a recent study using mainly protease inhibitor–based therapy in HIV KS.

Intimately linked with initiation of ARVs is the development of immune reconstitution inflammatory syndrome (IRIS). KS IRIS refers to the worsening of existing KS or the development of new KS lesions (cutaneous or visceral) in the first two months after initiating ARVs. This is in association with rapidly declining HIV viral load and improving

---

**Box 2. Steps to Diagnosing a Patient with Kaposi’s Sarcoma**

- Patient complains of skin lesions, or lesions are found incidentally during routine consultation.
- Examine skin for violet-colored macules, plaques, nodules, and tumors that are firm and nontender (Plate 1).
- Look at oral mucosa and conjunctivae (Plate 6).
- Palpate skin of limbs for nonpitting edema (lymphedema) (Plate 7).
- If lesions are fungating, they have typical odor caused by superinfection (Plate 5).
- Examine chest and abdomen; feel for lymph nodes, liver, and spleen.
- Assess for other opportunistic infections (e.g., PCP).
- Certain basic investigations are essential to confirm diagnosis and assess extent of disease. They are important for staging the disease so that appropriate therapy can be identified. These investigations are:
  - biopsy,
  - stool sample for occult blood,
  - chest X-ray,
  - HIV test,
  - CD4 count, and
  - full blood count.
It is well established that HIV-associated KS is not a curable disease. Therefore, the main objectives of therapy in patients with HIV Kaposi's sarcoma are as follows:

- Palliation and symptomatic management in patients with disseminated disease
- Improvement of pain associated with lymphedema
- Maximum possible resolution of disfiguring cutaneous lesions
- Resolution or slowing growth of visceral lesions
- In all cases, improving the patient’s quality of life

Figure 1 illustrates the approach to therapy of a patient once diagnosed with KS.

### STAGING OF KAPOSI’S SARCOMA

KS can be divided into good or poor prognosis disease according to AIDS Clinical Trials Group (ACTG) criteria that classify disease stage according to the extent of tumor, immune status, and severity of systemic illness (Table 1). When these criteria were first validated, it was found that the combination of tumor state and immune status (as quantified by CD4 count) were predictive of patient survival. However, a more recent evaluation of the ACTG criteria in the context of ART found that the combination of advanced tumor state and systemic disease were predictive of a poor prognosis.

For practical purposes, it is helpful to divide patients with Kaposi’s sarcoma into the following two categories so that appropriate and specific therapy can be planned:

- Localized disease—restricted to the skin only or skin and lymph nodes; lymphedema restricted to distal extremities or KS sites; nonobstructive or asymptomatic oral or other visceral disease
- Advanced disease—lymphedema of entire limb; symptomatic or obstructive visceral involvement

### THERAPY

It is well established that HIV-associated KS is not a curable disease. Therefore, the main objectives of therapy in patients with HIV Kaposi’s sarcoma are as follows:

- Palliation and symptomatic management in patients with disseminated disease
- Improvement of pain associated with lymphedema
- Maximum possible resolution of disfiguring cutaneous lesions
- Resolution or slowing growth of visceral lesions
- In all cases, improving the patient’s quality of life

Figure 1 illustrates the approach to therapy of a patient once diagnosed with KS.

### Localized Therapy

For disease localized to skin and mucous membranes, the aim is to treat the patient with ART alone for as long as possible. If the disease is still in an early stage, improvement can be expected after approximately six months once the CD4 count has increased. Initially, it is important to review patients at least monthly and advise them to return if the lesions are increasing in size. Increasing size of existing lesions and development of new lesions should be monitored because they can signal the
manifestation of IRIS. If IRIS occurs, patients will require chemotherapy while continuing to take ARVs.

For disease that does not respond to ART alone and is localized to the skin and mucosa, localized forms of therapy are indicated. It should be noted that intralesional chemotherapy with vinblastine, cryotherapy, or alitretino in gel are purely for cosmesis and do not control the underlying disease.

Vinblastine is one of the most widely used intralesional agents. It is cheap and effective, with a response rate of approximately 70%. Small, localized, cutaneous lesions as well as some mucosal lesions (e.g., on oral mucosa and eyelids) are amenable to therapy. Diluted with local anesthetic in a solution of 0.2 mg/mL and injected into the lesions, vinblastine induces necrosis and regression over a few days. A topical antibacterial cream used prophylactically prevents secondary infection. Among the drawbacks of most local therapies, including vinblastine, are that their effect is temporary and lesions may recur. In addition, patients should be advised of the postinflammatory hyperpigmentation that occurs as a result of therapy.

Cryotherapy using liquid nitrogen can be effective for small, isolated, disfiguring cutaneous lesions. Two freeze-thaw cycles applied to the lesions induces regression over a few days. The response rate is in the range of 80%, but associated complications include pain, secondary bacterial infection, relapse, and postinflammatory hypopigmentation. In dark-skinned individuals, the postinflammatory hypopigmentation is more obvious than the hyperpigmented violet-colored plaques, which blend in easily with the patient’s skin color.

Alitretinoin gel is a topical retinoid (9-cis-retinoic acid) preparation shown to be effective in inducing response four to eight weeks after treatment. However, it is expensive and induces
irritation, causing secondary leucoderma in dark-skinned patients. Thus, it is considered impractical in most resource-limited settings.

Radiotherapy
When patients have localized fungating tumors, localized lymphedema, or localized disfiguring cutaneous lesions that have not responded to the previously listed therapies, radiotherapy in addition to ART is appropriate. Radiotherapy is an important addition to ART and indicated when local KS-specific therapy cannot control the disease, yet the disease is not extensive enough to warrant chemotherapy.

A recent Cochrane Review assessed the effectiveness of current therapeutic regimens for HIV KS, with a focus on options available in resource-limited settings. The major selection criteria for this review were randomized controlled trials for HIV KS in adults. The main conclusions were that data from randomized controlled trials on effective treatments for HIV KS are scarce, particularly among people who are also taking ART. However, the review did show that alitretinoin gel is effective for therapy of cutaneous lesions, pegylated liposomal doxorubicin is effective for advanced KS, and radiotherapy is effective for treating cutaneous lesions. Apart from a randomized trial of radiotherapy, no trials applicable to resource-limited settings were identified.

With respect to radiation, the response to dosages of 20 gray (Gy) given in 10 fractions and 40 Gy given in 20 fractions were similar, and both dosages were slightly superior to treatment of lesions with a single dose of 8 Gy. In addition, radiotherapy is given to palliate patients with low CD4 counts (less than 50 cells/mm³) who require systemic chemotherapy but will not tolerate the side effects. It is also used as an adjunct to chemotherapy for localized tumors and painful lymphedema.

Systemic Therapy
For extensive lymphedema, symptomatic visceral disease, and KS immune reconstitution, chemotherapy is the treatment of choice. Therapy can be given as either single-agent vincristine (2 mg) or, if available, a combination of vincristine, doxorubicin (10 mg/m²), and bleomycin (10 mg/m²), also known as ABV therapy. Chemotherapy can be administered at two to three weekly intervals until response is achieved. Drug availability, cost, and patient CD4 count will dictate which regimen is chosen. One study used the following guide in the absence of ARVs:
- CD4 count greater than 100 cells/mm³: ABV, as described
- CD4 count of 30 to 100 cells/mm³: vinblastine 6 mg/m² and bleomycin

Etoposide
The effectiveness of oral etoposide as a treatment for systemic KS in resource-limited settings has been documented. Its activity may be antiangiogenic and used over a long period at low doses, and it can be given as metronomic therapy. Low doses can be given orally at 50 to 100 mg daily, depending on body mass, continuously for three weeks of the month; patients should be reassessed monthly. This regimen is especially appropriate in resource-limited settings where intravenous chemotherapy is expensive and labor intensive. For ABV therapy, patients require cardiac assessment prior to doxorubicin infusion. Patients respond well to this regimen over time, and for the nonresponders, etoposide phosphate can be used. ABV chemotherapy also remains an option.

In our center in Durban, South Africa, chemotherapy is withheld when a patient’s CD4 count is less than 200 cells/mm³. These patients continue on ARVs until their CD4 count improves, when they are better able to tolerate chemotherapy and
Paclitaxel
Paclitaxel is a relatively new agent shown to be effective and safe for HIV KS patients who require chemotherapy. It is administered in a dose of 100 mg/m² over three hours every two to three weeks and must be administered with intravenous dexamethasone to avoid allergic reactions. Concerns regarding its use include long infusion time, side effect profile, exacerbation of KS with steroid use, and prohibitive cost in resource-limited settings. Because of its high cost, paclitaxel, like pegylated liposomal doxorubicin, is generally not affordable or accessible to public-sector patients in resource-limited settings.

CONCLUSION
The high rates of HIV infection coupled with the high background seroprevalence of HHV-8 across sub-Saharan Africa set the stage for KS to continue to represent a significant public health threat into the foreseeable future. The currently low coverage of ARVs in many settings will only exacerbate the situation. Health-care professionals can play a pivotal role in managing KS through increasing awareness and prevention, as well as through ensuring early diagnosis, therapy, and palliation of late-stage disease.

REFERENCE LIST

ANY PEOPLE LIVING WITH HIV ARE confronted with gastrointestinal problems at some point during the course of their infection. Such problems include oral lesions, esophageal problems, nausea/vomiting, chronic diarrhea, and abdominal pain. Gastrointestinal infections in the immunocompromised host continue to have significant morbidity and mortality throughout the world. Gastrointestinal syndromes are of critical importance in HIV care because they interfere with the patient’s nutritional status and can considerably decrease quality of life. Gastrointestinal symptoms are also challenging for the clinician, as they can occur as side effects of HIV therapy as well as due to conditions related and unrelated to HIV.

This chapter is a syndrome-based guide to the management of gastrointestinal problems. A syndromic approach is recommended given that multiple enteric complications may coexist and one organism may produce several different clinical syndromes. A syndromic approach provides caregivers in resource-limited settings with the essential tools to identify and treat the most common problems based on clinical signs and/or simple laboratory findings. For each clinical syndrome, a flowchart algorithm for diagnosis and treatment is provided. These algorithms are not exhaustive and should be adapted for use in a particular setting based on local HIV prevalence and diagnostic capabilities. Further information regarding differential diagnosis is presented separately as a table. At the end of each section, practical tips on symptom relief and information for patients on preventive measures are given. All recommendations in this chapter are for the immunocompromised, and as such, non-HIV-related diseases are not discussed.

ORAL LESIONS

Incidence and Significance of Symptoms
Oral problems occur frequently in people with HIV disease. In the pre-antiretroviral therapy (ART) era, approximately 40% to 50% of patients developed oral fungal, bacterial, or viral infections over the course of their disease, and oral manifestations still are one of the earliest manifestations of immune deficiency in people living with HIV. Although there are considerable regional variations in the prevalence of the various oral manifestations of HIV infection, it is clear that oral candidiasis is one of the most frequent infections occurring during the course of HIV disease on all continents. Prevalence of oral candidiasis among people living with HIV ranges from 11%

             - Improvement continue until symptoms gone
             - No improvement fluconazole 200 mg daily
           - Vesicles/ulcers?
             - Presumptive herpes simplex painkiller topical antiseptic acyclovir 200–400 mg 5 × daily 1 week
               - Improvement continue until symptoms gone
               - No improvement presumptive aphthous ulcers prednisolone 40 mg daily 1 week
to 90%, depending on the study population and the variability of the diagnostic tools used in the various studies. Because oral candidiasis is common and can recur frequently, it is often the first physical manifestation of HIV disease. It may also be a valuable clinical indicator of virological and immunological failure of patients on ART.

Physical examination should include an inspection of the oral cavity, even without the presence of symptoms. Oral lesions can significantly affect quality of life in people living with HIV and can interfere with their ability to chew solid foods, leading to weight loss and malnutrition. Most mouth lesions have a prognostic value and are helpful in determining the stage of HIV disease because they are correlated with the patient’s CD4 count.

Symptomatic Care

*Mouth Care*
- Remove bits of food stuck in the mouth with a soft cloth soaked in salted water.
- Avoid dry mucous membranes—regularly rinse the mouth with warm salty water (one-half teaspoon of salt in a cup of water) or take frequent sips of diluted fruit juices and chew on sugarless gum or candy.
- Patients who have candidiasis under a denture or partial denture should remove the prosthesis before using topical agents. At bedtime, the prosthesis should be placed in a chlorhexidine solution until reinserting it into the mouth.

*Pain Relief*
- Take a nonsteroidal anti-inflammatory drug (NSAID) or apply lidocaine mouth gel.
- Mix two tablets of aspirin in water and rinse the mouth up to four times daily.
- Modify food intake—eat more frequent, smaller meals.
- Avoid foods or liquids that are very hot in temperature or very spicy.

Preventive Measures
- Herpes simplex is easily spread through kissing. If mouth or lips have visual lesions, kissing should be avoided.
- Bleeding gums may transmit HIV during “deep kissing” or oral-genital contact. Advise patients to avoid exposing partners to HIV by taking all necessary precautions, including abstaining from risky activities until their condition has been cured.
- Patients should maintain good oral hygiene by using a soft toothbrush on teeth, gums, and tongue after each meal or at least three times a day. They should rinse their mouth with warm salty water (one-half teaspoon of salt in a cup of water) after eating and between meals.

ESOPHAGEAL PROBLEMS

Esophageal problems in people living with HIV include difficulty swallowing (dysphagia) or midline retrosternal pain when swallowing (odynophagia). Odynophagia and dysphagia cause significant discomfort and, if left untreated, may result in scarring of the esophagus, dehydration, and weight loss. Most esophageal conditions are an indication of severe immunosuppression (World Health Organization stage IV) and are therefore an indication for ART. ART has been shown to reduce esophageal opportunistic infections in HIV patients compared with patients who are not receiving therapy. The exact prevalence of esophageal infections is unknown, and not all patients with esophagitis are symptomatic. However, esophageal complaints are common in HIV-infected patients, occurring in at least one-third of patients at some point during the course of their disease. The majority (50% to 70%) of patients with dysphagia or odynophagia have candidal esophagitis alone or in association with other infectious pathogens.

  improvement no improvement

  stop steroids, symptomatic treatment

- follow up

* If patient is severely ill or suffers from systematic symptoms such as weight loss, night sweats and particularly fever: exclude systematic infection (TB, CMV) before giving steroids.
Diet and Lifestyle

Patients should do the following:

- Test their ability to swallow with a small amount of water before each feeding to avoid aspiration of food.
- Eat slowly in the upright position and do not bend over or lie flat soon after eating.
- Avoid eating too late at night.
- Raise the head of the bed so that the patient is lying in an upright position. (This can be achieved by placing a block under the bed legs at the head of the bed or by placing some pillows between the mattress and the bed frame at the head of the bed.)
- Maintain adequate caloric intake by taking small but frequent meals containing cool and soft foods and avoiding foods and drinks that are known to cause or worsen odyno-/dysphagia (e.g., spicy, fatty, or fried foods; chocolate; caffeinated drinks or alcohol).
- Try to stop smoking.
- Wear clothes that are loose fitting around the stomach.

Medication

- Stepwise analgesia but avoid NSAIDs.
- Magnesium hydroxide—two tablets after each meal and at bedtime to neutralize acid. When patients are on ART or take other medication for opportunistic infections, it is advised to leave at least one hour between taking these medications and the magnesium hydroxide (since many of these drugs require an acid pH to work properly).

Preventive Measures

See recommendations for oral lesions.

NAUSEA AND VOMITING

Nausea, vomiting, or both are very common symptoms in any stage of HIV infection but rarely dominate the clinical picture. Nausea is a common adverse effect of many antiretroviral...
of note, various clinical studies indicate a lower prevalence of *Helicobacter pylori* infection in HIV patients. This is relevant because in the general population, gastritis due to *H. pylori* is the most common cause of nausea.

### Symptomatic Care

#### Diet and Lifestyle

Patients should stay nourished and well hydrated even if they are experiencing nausea and vomiting. Eating small, frequent meals may be best tolerated, while avoiding dairy products, greasy and spicy foods. Seek locally available drinks and foods that the patient likes. Ginger may help.

Patients should avoid smoking and drinking coffee or alcohol.

Medication
It is important to stress to patients that they cannot stop taking any of their medications because of vomiting. If vomiting occurs within one hour of taking ARVs, another dose should be taken.

Patients may take metoclopramide (10 mg every eight hours) to relieve symptoms.

CHRONIC DIARRHEA
Chronic diarrhea is defined as more than three loose stools a day for more than one month. Despite the decreased incidence of this condition since the advent of effective antiretroviral drugs, it remains a very common clinical presentation in HIV-infected people and may have a variety of causes. Before the widespread availability of combination ART, chronic diarrhea was reported to occur in 40% to 90% of HIV-infected patients, with large variations in pathogens and among studies. Prevalence of diarrhea tended to be particularly high in communities with overcrowding and/or poor sanitation and limited access to clean water. Diarrhea may cause deterioration of appetite and therefore malnutrition as well as malabsorption, with subsequent dehydration and weight loss. Persistent diarrhea may also have a significant impact on patients' quality of life and may interfere with adherence to and efficacy of ART. In areas where both financial and human resources are limited in providing adequate care, it is associated with significant morbidity and mortality rates.

Chronic diarrhea is more common in patients with low CD4 counts, signaling advanced immunosuppression. Some organisms, such as microsporidia, usually cause diarrhea only in the immunosuppressed; others, such as Cryptosporidium, Salmonella, Shigella, and Campylobacter, which can cause diarrhea in the immunocompetent population, produce more severe or prolonged infections in people living with HIV. Because treatment options vary widely depending on the infectious agent, microbiologic evaluation is warranted. However, the isolation of the underlying causative agent is possible in only 40% to 60% of patients who present with chronic diarrhea in sub-Saharan Africa and Asia. Therefore, familiarity with the most common pathogens in the clinician’s region will help with diagnosis and treatment. For patients taking ARVs (especially PIs) in whom no infectious agent can be found, diarrhea may be due to the medication.

Some of the infectious agents can also cause acute self-limiting diarrhea (e.g., bacterial enteritis). Cases of principally acute diarrhea in HIV-infected people do not require a different approach than those in uninfected people. However, monitor closely and ensure adequate fluid intake and continuation of ARVs.

It should be noted that cases of principally acute diarrhea in HIV-positive individuals can be managed in the same way as chronic diarrhea. However, such patients should be monitored closely to ensure adequate fluid intake and continuation of ART.

Symptomatic Care

Diet and Lifestyle
- Patients with severe diarrhea must maintain adequate hydration. Encourage drinking frequent small amounts of (rice) soup, porridge, water, or oral rehydration solution. Patients should avoid high-sugar drinks, caffeinated beverages, and alcohol and should drink at least 200 mL extra on top of normal fluid intake after each unformed stool.
- Encourage frequent intake of easily digested foods such as bananas (rich in potassium), rice and potatoes (reduce diarrhea), boiled vegetables, crackers, and carrot soup (replaces minerals and vitamins). Patients should avoid high-fiber foods, greasy, spicy, or raw foods, and dairy products. Nutritional support is very important to avoid wasting. At least 2,500 kcal daily are needed.
- In case of cramps, avoid beans, cabbage, cauliflower, spices, and carbonated drinks.

*Source: Adapted from Lynen.¹⁹*

*Studies in Lima, Peru, and Nairobi, Kenya, have reported high resistance rates of bacterial pathogens to cotrimoxazole.⁵⁰⁻⁵¹*
Abdominal pain is frequent in people living with HIV; one study in South Africa reported a 45% prevalence of abdominal pain among HIV-positive outpatients. In that study, abdominal pain was associated with poor survival. Abdominal pain can occur at any stage of HIV infection, but etiology will differ according to immune status and geographic location. It is a challenging problem for the clinician because it can be caused by very benign as well as very serious etiologies. Abdominal pain in HIV patients is often a marker of an underlying opportunistic pathologic condition. In areas of high TB prevalence, abdominal pain should be highly suspected as a sign of disseminated TB infection. Patients on ART can also suffer from various side effects that provoke abdominal pain.

**Symptomatic Care**

*Diet and Lifestyle*

In case of cramps, avoid beans, cabbage, cauliflower, spices, and carbonated drinks.

**Medication**

Pain relief:

- Step 1: nonopioid (e.g., aspirin, paracetamol, NSAID)
- Step 2: weak opioid (e.g., codeine) +/− step 1
- Step 3: strong opioid (e.g., morphine/tramadol) +/− step 1

The following adjuvants may be added:

- For cramps: codeine 30 mg every four hours or hyoscine 10 mg three times daily or loperamide 2 to 4 mg four times daily
- For visceral pain: prednisone 10 to 80 mg daily for one week

**Preventive Measures**

See section on diarrhea.

---

**Preventive Measures**

Provide devices for incontinence (e.g., protective bed coverings, sheets, etc.) to prevent soiling.

Ensure good anal care. Clean anal area with soft tissue after passing stool, wash with water and soap if necessary, and apply petroleum jelly or sit in a basin of water with a pinch of salt twice daily.

CONCLUSION
Because the majority of people living with HIV are confronted with gastrointestinal problems at some point during the course of disease, and because those conditions are a significant cause of morbidity and mortality throughout the world, dealing with them properly is of critical importance in comprehensive HIV care. With the advent and increasing availability of combination ART, HIV is gradually becoming a manageable chronic disease. Gastrointestinal symptoms can interfere with the patient’s nutritional status and can considerably decrease the quality of life. As such, neglecting such symptoms, whether they are due to medication side effects or disease progression, will decrease the overall quality of HIV care.

Although gastrointestinal symptoms may be challenging to diagnose and manage due to multiple etiologies, it is highly important to follow them closely and to consider any and all causes of gastrointestinal discomfort. Additionally, any clinical feature related to the gastrointestinal tract is an important opportunity for the clinician to discuss nutritional status, fluid intake, feeding habits, hygiene, and adherence to ARVs with the patient.

ACKNOWLEDGMENTS
The recommendations in this chapter are largely adapted from the guidebook Clinical HIV/AIDS Care Guidelines for Resource-Poor Settings, 2nd ed., by Lut Lynen (Brussels, Belgium: Médecins Sans Frontières; 2006).
REFERENCE LIST

18. Van Roey J, Haxaire M, Kamya M, Lwanga I, Katabira E. Comparative efficacy of topical therapy with a slow-release mucoadhesive buccal tablet containing miconazole nitrate

DISEASES AFFECTING THE SKIN AND oral mucosa affect approximately nine of ten people living with HIV. Cutaneous manifestations may be the initial indication of a diagnosis of HIV infection, especially in cases when the host immunity is still relatively robust (as is often the case with herpes zoster). These manifestations may also occur further along in the course of HIV infection as immunity begins to decline (as with seborrheic eczema) or as a manifestation of full-blown AIDS. These conditions can also serve as markers of severe immunodeficiency, which if left untreated can be fatal (as in histoplasmosis).

As with other systems, several signs of immune deficiency can manifest in the skin. As CD4 counts decline and patients suffer with more severe immune deficiency, multiple skin pathologies will present. These may require longer periods of therapy and can relapse more frequently than pathologies occurring in HIV-negative individuals.

Thus, the importance of having a thorough working knowledge of the cutaneous manifestations of HIV/AIDS cannot be overemphasized for those working with HIV-infected individuals. Skin disease, although not a common cause of mortality, is a significant cause of morbidity and thus requires timely recognition and appropriate therapy to significantly improve quality of life for the affected person. Appropriate and timely diagnosis and treatment is even more critical in resource-limited settings, where patients often have limited access to antiretroviral therapy and therefore may suffer from the manifestations of immune deficiency for prolonged periods.

**CUTANEOUS MANIFESTATIONS OF HIV INFECTION**

The most common cutaneous manifestations of HIV infection are described here and summarized in Table 1, while cutaneous AIDS-defining conditions are described in Box 2.

**Infections and Infestations**

Infections and infestations form the largest group of cutaneous manifestations of HIV. This group comprises fungal, viral, bacterial, and parasitic infestations. Infections occurring in HIV-infected individuals are usually common in the general population but in the immunocompromised individual tend to be more severe and more resistant to conventional therapy, may be prone to more frequent relapses, and may require recurrent courses of therapy (e.g., oral candidiasis). Some conditions, such as cutaneous...
cryptococcosis, are peculiar to immunosuppression, and their presence necessitates further investigation.

**Inflammatory Conditions**

The most common conditions in this group are the seborrheic eczemas, pruritus, xerosis, and papular eruptions. Although not associated with mortality, these conditions are extremely debilitating to the individual, and simple measures can be taken to significantly improve quality of life.

**Tumors**

Kaposi’s sarcoma, as well as Hodgkin’s and non-Hodgkin’s lymphomas, can present on the skin and can be diagnosed based on characteristic presentations, aided by histopathology. These are described elsewhere in this text and will therefore not be discussed here.

### An Algorithmic Approach to Skin Manifestations of HIV

The cutaneous manifestations of HIV have always been classified etiologically. In contrast, this chapter classifies them according to lesion type (i.e., morphologically) as an aid to readers who have no specific training in diagnosing skin conditions.

The sections that follow cover six categories of cutaneous lesions: plaques, nodules, oral mucosal lesions, papules, blisters, and ulcers. Each section begins with an algorithm to assist in diagnosing the more common morphologically related skin conditions, followed by brief descriptions of possible etiologies and recommended therapy. Color plates featuring photographs of these various conditions are included at the end of this chapter. The categories of lesions described are defined as follows:

---

<td>dryness of the skin</td>
</tr>
</tbody>
</table>

---
• Plaques: solid, flat lesions more than 2 cm in diameter (e.g., psoriasis)
• Nodules: solid, rounded lesions more than 0.5 cm in diameter (e.g., Kaposi’s sarcoma)
• Oral mucosal lesions: plaques on tongue or buccal mucosa
• Papules: solid lesions less than 0.5 cm in diameter (e.g., molluscum contagiosum)
• Blisters: clear, fluid-filled lesions (e.g., herpes zoster)
• Ulcers: breaches in the epidermis of the skin (e.g., aphthous ulcers)

**PLAQUES**

*Seborrheic Eczema*[^16]

Seborrheic eczema (Plates 1a–1d) is one of the conditions most commonly associated with HIV. Although it can occur at any CD4 count, it tends to become more severe and recalcitrant to therapy as the CD4 count declines.[^3] It begins insidiously with plaques, weeping, and pruritus involving the scalp and flexures (i.e., axilla, inframammary, groin, and retroauricular folds). The scalp has yellow, greasy scales, and the flexures are erythematous and often secondarily infected. It may be difficult to distinguish from flexural psoriasis, and the clinician should look for the distinguishing features of psoriasis. In infants, it may present as erythroderma (i.e., redness and scaling of more than 90% of the body) or napkin dermatitis. As the child grows, it presents in the adult form but heals with hypopigmentation.

*Therapy*[^4]

If infected (i.e., weepy and malodorous), treatment begins with a systemic broad-spectrum antibiotic, such as erythromycin 500 mg four times a day for seven days, and potassium permanganate ($\text{KMnO}_4$) soaks. That is followed with specific therapy such as topical corticosteroids (1%...)

### Box 2. AIDS-Defining Skin Conditions

- Kaposi’s sarcoma
- Histoplasmosis
- Cryptococcosis
- Herpes simplex ulcers for more than one month
Figure 1. Algorithm for the diagnosis of patients presenting with plaques
Psoriasis

Psoriasis (Plates 2a–2c) can occur in the severely immunocompromised patient. It may present as psoriasis vulgaris (i.e., well-defined erythematous plaques with silvery scales involving the extensors) or as flexural lesions, which can overlap with seborrheic eczema or as erythroderma. Clues to psoriasis include silvery scaling, scalp involvement, nail changes (e.g., pitting and onycholysis), and joint pain. Psoriasis in HIV-infected individuals tends to be hyperkeratotic or rupioid and unstable (i.e., tending toward erythroderma), and the affected individuals are more likely to develop arthritis.10,11

Therapy

If localized, topical therapy can be used as follows:

- **For face, flexures, hands, and feet:** topical corticosteroids, such as 1% hydrocortisone for the face, methylprednisolone aceponate cream or betamethasone valerate [one-third strength] for face and body, ketoconazole shampoo, antihistamines (e.g., chlorpheniramine maleate 4 mg via transdermal delivery system [TDS], hydroxyzine 25 mg TDS, or promethazine 25 mg nightly).

Ichthyosis

Ichthyosis is common in the presence of any chronic disease or malnutrition and as such is also commonly found in people living with HIV. It presents with “fishlike” scales on the extensors of the lower limbs but may progress to involve the upper limbs and trunk. It may be associated with pruritus and xerosis. Xerosis is common in HIV, seen in approximately 30% of patients, whereas pruritus is seen in advanced disease and is a marker of disease progression because it commonly occurs in patients with CD4 counts less than 50 cells/mm³.1,3

Pruritus in the HIV-infected individual may have various cutaneous and systemic causes, including cutaneous infestations with scabies or insect bites, inflammatory conditions like drug reactions and papular eruptions, iron deficiency, or more sinister malignancies like Hodgkin’s or non-Hodgkin’s lymphoma. In addition to searching for an underlying cause, therapy should aim at relieving the pruritus.7,9

**Therapy**

Therapy is aimed at moisturizing the skin with emollients. A combination of white soft paraffin and liquid paraffin in a 50:50 mixture or 2% salicylic acid should be applied twice a day. Antihistamines, such as chlorpheniramine maleate 4 mg TDS, hydroxyzine 25 mg TDS, or promethazine 25 mg nightly, can also be used.

If the patient is still symptomatic, amitriptyline 25–75 mg nightly can be added.

Photodermatitis

Individuals whose immunity is declining are prone to photosensitivity that may be worsened by certain drugs (e.g., tetracyclines, antituberculosis therapy). People with this condition complain of burning or pruritus of the sun-exposed areas (i.e., the face, “V” and nape of the neck, extensors of the arms, and in females, extensors of the lower legs). Areas of sparing include the upper eyelids, retroauricular area, and under the chin. If left untreated, the condition may progress to a chronic lichenified eczema (i.e., thickening, hardening, and darkening of the skin) involving the affected areas. With constant scratching, secondary infection may occur, leading
to depigmentation caused by the inflammation (Plates 3a–3b).

**Therapy**

Topical corticosteroids, such as 1% hydrocortisone, are effective for the face; methylprednisolone acetate or betamethasone valerate can be used at one-third strength for the face and body.

Antihistamines (e.g., chlorpheniramine maleate 4 mg TDS, hydroxyzine 25 mg TDS, or promethazine 25 mg nightly) can also be used.

Sun avoidance and regular use of sunscreen are mandatory.

**Tinea Infections**

Dermatophyte (fungus parasitic on the skin or skin derivatives) infection, which presents as “ringworm,” occurs more frequently in HIV-infected individuals. Infection presents in both children and adults as tinea corporis or ringworm of the glabrous (hairless) skin (Plates 4a–4b). The lesions are annular plaques that clear centrally and have an active border consisting of papules, vesicles, or excoriations. Lesions in HIV-infected individuals may be more extensive, atypical, nodular, and recalcitrant to therapy. Similar lesions occur on other sites of the body, such as the groin (tinea cruris), hands (tinea manum), feet (tinea pedis), and scalp (tinea capitis). On the hands and feet, scaling may occur, and the nails may also be affected. The nails are usually discolored, crumbly, and hyperkeratotic. Scalp involvement, or tinea capitis, typically presents as scaling, broken-off hairs, and cervical adenopathy. However, there may be secondary infection, pustules, and boggy plaques. Diagnosis can be confirmed under a microscope with the addition of potassium hydroxide (KOH 20%). Visualization of the hyphae in the keratin of the skin, hair, or nails will confirm the diagnosis. Scales, hair, or nail clippings can also be sent to the laboratory for direct microscopy and culture.

**Therapy**

Therapy for tinea corporis, cruris, manum, and pedis depends on the extent of the fungal infection.

If localized, topical antifungal creams (e.g., econazole, miconazole, clotrimazole, or terbinafine cream) can be given twice daily for 14 days.

If there is extensive skin, hair, or nail involvement, systemic antifungal therapy is required:
- Griseofulvin 1 g/day for 28 days and 20 mg/kg in children, or
- Itraconazole 200 mg/day for 5 days or 5 mg/kg in children, or
- Terbinafine 250 mg/day for 14 days for extensive tinea corporis. In children, 250 mg if child weighs more than 40 kg, 125 mg if 20–40 kg, and 62.5 mg if less than 20 kg; administer for 14 days for tinea corporis or 28 days for tinea capitis.

For tinea unguium (nail infection), the duration is much longer:
- Griseofulvin for 6 months for fingernails, 12 months for toenails, or
- Itraconazole 400 mg/day for 1 week every month and continued for 2 months for fingernails, 4 months for toenails, or
- Terbinafine 250 mg/day continuously for 6 weeks for fingernails and 12 weeks for toenails

If patients are on antiretroviral drugs (ARVs), especially non-nucleoside reverse transcriptase inhibitors (NNRTIs), the azole antifungals should be avoided. The least interaction is expected with terbinafine. However, if a few nails are affected (less than three), it is cost-effective to use topical therapy because it avoids the problem of drug interactions. A combination of 2% clotrimazole in 40% urea or amorolfine nail lacquer can be used.

**Drug Eruptions**

Drug eruptions (Plates 5a–5b) occur 100 times more frequently in HIV-infected individuals, with the probability of drug reactions increasing with advancing immunodeficiency. The most
Secondary Syphilis

Syphilis (Plates 6a–6e) can present as a variety of cutaneous lesions. The classical lesions of secondary syphilis are an asymptomatic papulosquamous truncal eruption, annular plaques (especially of the “muzzle” area of the face), split papules involving the angles of the mouth, snail track ulcers of the tongue, and hyperpigmented papules of the palms and soles. There may also be alopecia and/or lymphadenopathy. The rash of secondary syphilis in HIV-infected individuals may present as it does in the immunocompetent individual. However, there are some differences: more than one primary lesion, or primary and secondary lesions may coexist. Secondary lesions may be more aggressive, profuse, and ulcerated (i.e., lues maligna, a form of secondary syphilis) and there is a more rapid conversion from secondary to tertiary syphilis.

Diagnosis can be confirmed with nontreponemal tests (e.g., Wasserman reaction, rapid plasma reagin, and Venereal Disease Research Laboratory [VDRL]), but therapy should only be considered with titers greater than 1:8. The rate of false-negative serologies is higher when syphilis is strongly clinically suspected, and the treponemal tests are more sensitive. Lumbar puncture should be done for serology of the cerebrospinal fluid (CSF) because a positive CSF serology would require intravenous penicillin therapy.

Therapy

Therapy is aimed at identifying the causative drug and withdrawing it from use. For mild reactions, therapy with antihistamines and topical steroids is recommended.

When SJS or TEN is suspected, withdraw the most likely offending drug, monitor for sepsis, maintain fluid and electrolyte balance, dress denuded skin, and prescribe adequate analgesia.
NODULES

Papulopruritic Eruptions and Prurigo
Papulopruritic eruptions and prurigo (Plates 7a–7b) are itchy papules and nodules on the extensors of the limbs and the face. They are distressing to the patient, and repeated scratching leads to hyperpigmented nodules on a background of lichenification. Scratching and secondary infection may cause postinflammatory depigmentation. See the discussion of papular eruptions under “Papules” for a complete description.

Therapy
Therapy is aimed at relieving the pruritus:
- Hydration of the skin with emollients (e.g., 50:50 white soft paraffin and liquid paraffin)
- Topical corticosteroids
- Oral antihistamines

Scabies
Scabies are itchy papules and nodules involving the axillae, groin, or trunk with crusting and burrows of the web spaces of the hands and feet. These may be secondarily infected with purulent discharge. Patients presenting with itchy nodules should be given a therapeutic trial of antiscabies therapy (see “Papules”).

Cryptococcosis
Cryptococcosis (Plates 8a–8d) presents as non-itchy nodules of the skin and indicates an underlying systemic disease. In patients with advanced immunosuppression, disseminated, invasive fungal infection (most commonly, cryptococcosis) should be excluded because it can result in high mortality in HIV-infected individuals with CD4 counts less than 100 cells/mm³. Cutaneous involvement occurs in 10%–20% of individuals and usually represents hematogenous dissemination. The nodules typically appear on the face and scalp and are umbilicated or have central hemorrhagic crusts. In addition to the nodules, there may be papules, ulcers, pustules, plaques, and cellulitis. Any of the skin lesions in an ill patient should be biopsied and sent for histopathology and culture. The patient should be assessed for neck stiffness and should have a lumbar puncture to exclude cryptococcal meningitis.

Therapy
- Intravenous amphotericin B 1 mg/kg for 14 days followed by oral fluconazole 200 mg two times daily for 10 weeks, or
- Itraconazole 200 mg two times daily for 10 weeks

Secondary prophylaxis once the lesions are cured includes the following:
- Fluconazole (200 mg/day) or itraconazole (200–400 mg/day) until immunity has been restored (defined as CD4 count greater than 100–150 cells/mm³ for at least six months)¹⁹
If patients are on concomitant NNRTI therapy, itraconazole may reduce therapeutic levels, so fluconazole is preferred.

Histoplasmosis
Histoplasmosis (Plates 9a–9d) is an AIDS-defining, disseminated fungal infection associated with high mortality. It occurs with advanced immunosuppression, usually at CD4 counts less than 150 cells/mm³. Diagnosis is difficult because the condition can masquerade as tuberculosis. Patients are ill, pyrexial (feverish), have chest infiltrates, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities. The skin manifestations can be protean (i.e., papules, nodules, plaques, ulcers) but have a predilection for the oral and nasal mucosa. Condition should be suspected in patients who have not responded to treatment with antibiotics and antituberculous therapy. Biopsy and culture is mandatory for diagnosis.
Opportunistic Infections, Cancers, and Coinfections

It is a systemic illness that occurs with advanced immunosuppression (CD4 count less than 100 cells/mm³). The cutaneous lesions are angiomatic papules and nodules that are friable, exophytic, and surrounded by a collarette. Lesions vary in number and can present as abscesses and cellulitic plaques. Systemically infected patients present with fever, constitutional illness, hepatic and splenic peliosis, and even endocarditis. Biopsy and culture and blood culture are necessary for diagnosis.

Therapy
Administer amphotericin B intravenously at 3 mg/kg for 14 days. Follow with itraconazole 200 mg twice daily for 10 weeks, and then give 200 mg daily for patients in endemic areas or with CD4 counts less than 150 cells/mm³.

Bacillary Angiomatosis
Bacillary angiomatosis (Plates 10a–10b) is a spirochetal infection caused by Bartonella henselae.

Figure 2. Algorithm for the diagnosis of patients presenting with nodules

CXR = chest X-ray; LP = lumbar puncture; PPE = papulopruritic eruptions
Culture, however, is difficult and a therapeutic trial of antibiotic can be used (if diagnosis is in doubt) to differentiate from Kaposi’s sarcoma.

**Therapy**

- Erythromycin 500 mg four times daily for 8 to 12 weeks, or
- Doxycycline 100 mg twice daily for 8 to 12 weeks

**ERYTHEMA NODOSUM/INDURATUM**

Erythema nodosum (Plate 11) is characterized by painful nodules occurring most commonly on the shins of the lower limbs. Presence of nodules should prompt a search for underlying tuberculosis or disseminated fungal infection, which may cause ulcerating nodules on the calves (i.e., erythema induratum).

Management is aimed at searching for underlying causes, especially tuberculosis. A chest radiograph and Mantoux test are warranted. If no underlying cause is found, treatment with anti-inflammatories is recommended.

**ATYPICAL MYCOBACTERIA INFECTION**

Atypical mycobacteria infection (Plate 12) presents as tender subcutaneous nodules and abscesses with erythematous, pustular centers. The nodules and abscesses tend to ulcerate. Infection occurs in severely immunocompromised patients. A biopsy and culture is required for diagnosis. Often these patients have been prescribed antibiotics and antituberculous therapy without improvement. Therapy with antibiotics (e.g., minocycline, macrolides) is recommended.

**KAPOSI’S SARCOMA**

Kaposi’s sarcoma (Plate 13) is a constellation of violet-colored asymptomatic macules, plaques, nodules, and tumors. They may present insidiously, and early lesions may be difficult to diagnose in dark-skinned patients. However, they are usually symmetrical, have a predilection for the lower limbs, follow the skin creases on the trunk, involve the hard palate, and present commonly with gastrointestinal tract and chest involvement. It is important to recognize and confirm lesions on biopsy because they are AIDS-defining and thus patients are eligible for antiretroviral therapy. Kaposi’s sarcoma is discussed in more detail elsewhere in this text.

**LYMPHOMA**

Patients living with HIV who have generalized lymphadenopathy and nontender, nonpruritic nodular lesions that have a tendency to ulcerate should have a biopsy to exclude lymphoma (Plates 14a–14c).

**MUCOSAL LESIONS**

**Candidiasis**

Candidiasis (Plate 15) is one of the most common mucocutaneous manifestations of HIV infection and is a marker of progression to AIDS. In children under six months, it should be taken into consideration with other signs of immunodeficiency. In addition, mucocutaneous candidiasis in children can present as diaper and flexural lesions and paronychia. The spectrum of cutaneous lesions is onychodystrophy, paronychia, urethritis, and intertriginous lesions. Disseminated skin lesions may occur in severely immunosuppressed patients and present as pustules or nodules on an erythematous base with or without central necrosis.

Among the several types of oral candidiasis, the most common is the pseudomembranous type, which presents as painful, whitish plaques of the
Attention to xerostomia (dry mouth) is important in all oral conditions; thus, using a fluoride or chlorhexidine mouthwash is important to ensure good oral hygiene and to prevent recurrences.

**Therapy**

Therapy with topical antifungals is recommended unless there is esophageal involvement or recurrent poor response to topicals.

- Gentian violet 0.5% TDS (although messy) is effective
- Oral nystatin suspension (“swish ‘n’ swallow”), lozenges, or troches for 10 to 14 days
- Fluconazole or itraconazole 200 mg daily for five to seven days

---

**Figure 3. Algorithm for the diagnosis of patients presenting with mucosal lesions**

- **Plaques on tongue or buccal mucosa**
  - Pseudomembranous candidiasis: whitish, painful, adherent, cottage cheese–like, erythematous base
  - Hyperplastic candidiasis: whitish-yellowish on either side of tongue or buccal mucosa
  - Kaposi’s sarcoma: violet-colored plaques, nodules on tongue, palate, gingiva
  - Oral hairy leukoplakia: corrugated, whitish ridges on sides of tongue, adherent

- **Painful ulcers**
  - Herpes simplex: shallow, irregular border, yellowish base on lips, tongue, hard palate
  - Aphthous ulcers: well defined, deep, whitish base, erythematous halo on soft palate, buccal mucosa, tongue, tonsils

- **Tongue, uvula, and buccal mucosa (resembling cottage cheese).** Removal of the plaques with a gauze or spatula will reveal an underlying erythematous base. The erythematous type of candidiasis presents as erythematous macular lesions on the dorsum of the tongue, without plaques. Hyperplastic candidiasis presents as yellowish plaques on the lateral borders of the tongue, while candidiasis can also present as angular cheilitis or fissuring at the angles of the mouth, which is painful. In general, oral candidiasis is asymptomatic, but patients may complain of pain, burning, and dysphagia. Pain on swallowing signals the possibility of esophageal involvement. Vulval candidiasis presents with pruritus, burning, and a whitish discharge.
If there is no response to fluconazole, resistance should be suspected. In cases of fluconazole resistance, amphotericin B may be effective.¹²

**Oral Hairy Leukoplakia**

This is an asymptomatic condition that presents as white corrugated ridges along the lateral surface of the mouth. It is caused by the Epstein-Barr virus and is associated with advanced HIV disease.¹⁸

**Therapy**

Therapy is generally not indicated, but if symptomatic, one of the following can be used:
- Topical podophyllin or tretinoin gel
- Oral acyclovir 800 mg TDS for 10 days

**Aphthous Ulcers**

Aphthous ulcers (canker sores) can present in persons infected with HIV, but their presence should not be taken as a sign of immunosuppression because the ulcers are common in the general population. Presenting as painful and recurrent, the ulcers can be very difficult to distinguish from herpes simplex infection. They can be single or multiple and are well defined with a whitish base and surrounding erythema. Aphthous ulcers are usually deeper than herpes simplex ulcers and typically occur on the soft palate, tongue, buccal mucosa, and tonsils.

**Therapy**

Therapy is symptomatic and aimed at keeping the mouth clean and analgesic to allow the ulcers to heal. If the ulcers are large and/or persistent, or if herpes simplex is suspected as a cause, therapy with acyclovir 400 mg TDS may be given. Other recommended therapy includes the following:
- Analgesics (e.g., paracetamol or combination preparations)
- Topical lignocaine (lidocaine) gel
- Oral antihistamines alleviate the pruritus.
- All household contacts should be treated.
- Secondary bacterial infections, if present, should be treated first with appropriate antibiotics.
Figure 4. Algorithm for the diagnosis of patients presenting with papules

In HIV-infected persons, scabies may be resistant to treatment and require repeated courses of the scabicide.

Topical scabicides include the following:
- Benzoyl benzoate (25%) lotion should be applied twice, from neck to toes, after a bath on the first day. On the second day, two applications are reapplied from neck to toes, but the patient should not bathe. On the third day, a bath should be taken and all clothes and bed linen should be washed and dried in the sun.
- Sulfur (5%) ointment recommended for children under the age of two. Ointment should be applied daily for five days.
- Permethrin (5%) lotion is applied and left overnight; repeated applications may be required, usually one week after the initial application. Permethrin should not be used in infants younger than two months of age or in pregnant or nursing women.
- Lindane 1% (gamma benzene hexachloride) is effective but may cause neurotoxicity. An application of lindane is left on the patient for eight hours and then washed off. Repeated applications after seven days may be required in some patients. Lindane should not be used in children, pregnant females, lactating mothers, and patients with neurological disorders.20

Management of Norwegian (Crusted) Scabies
Pretreatment with keratolytic creams, such as creams or ointments containing salicylic acid, may be helpful. The scabicide should be applied on the scalp and face (avoid the eyes, nose, and mouth). Patients with crusted scabies should first be treated with a preparation of 5% sulphur and 5% salicylic
acid in emulsifying ointment to treat any secondary infection and debride the lesions. After the lesions have been debrided (usually 10–14 days), benzyl benzoate lotion can be used. Oral ivermectin is the drug of choice for crusted scabies and is administered at 200 µg/kg as a single dose.20

**Papulopruritic Eruptions of HIV**

Papulopruritic eruptions (Plates 17a–17b) and eosinophilic folliculitis are distinct clinicopathological entities seen in HIV-infected patients. This chapter refers to both as papulopruritic eruptions (PPE) of HIV. Clinically, the patients present with excoriated widespread pruritic papular lesions. The papules are symmetrical, involving the limbs, trunk, face, and neck; the web spaces, mucous membranes, palms, and soles are spared. More than 50% of HIV-infected patients report PPE as the first presenting feature of HIV infection.24

**Therapy**

Sedating oral antihistamines, such as hydroxyzine or chlorpheniramine, alleviate the pruritus. Potent topical steroids, such as methyl prednisolone aceponate or dilute betamethasone cream, used alone or together with oral antibiotics (e.g., metronidazole or tetracyclines) are usually effective. Short courses of systemic steroids, such as prednisone given at 70 mg and gradually reduced by 5 to 10 mg over a period of 7 to 14 days, have been reported to be effective. However, systemic steroids should be used with caution in immunosuppressed patients. Phototherapy, if available, is useful for resistant cases.25

**Papular Urticaria**

Papular urticaria (Plates 18a–18b) presents with pruritic, excoriated papules, usually on exposed sites. This exaggerated insect bite reaction may be indistinguishable from PPE. A history of insect bites will favor the diagnosis of papular urticaria. In addition, the lesions tend to be in groups or in a linear pattern.

**Therapy**

- Protective measures against insects (e.g., insect repellents, bed nets)
- Topical steroids and oral antihistamines
- Systemic steroids in severe recalcitrant cases, but long-term use of systemic steroids by HIV-infected patients may result in serious complications.26

**NON-ITCHY PAPULES**

**Human Papillomavirus Infection**1,2

Human papillomavirus (HPV) can cause numerous manifestations in the HIV-infected individual (Plates 19a–19b). These include verruca vulgaris (common warts), widespread plane warts, and condyloma acuminata. The warts can be single but are usually multiple, large, and disfiguring in patients with HIV infection.27

HPV infection has been associated with anogenital cancer. Cervical cancer is the most common malignancy in women in the developing world and there is a higher incidence of cervical intraepithelial neoplasia in HIV-infected women. Thus, appropriate screening for cervical cancer is important in HIV-infected patients.

The spread of HPV infection is associated with higher numbers of sexual partners and lack of condom use; preventive measures should focus on addressing those issues.28

**Therapy**

Treatment is usually less effective in HIV-infected patients, and repeated treatment courses are often required. Several modalities of treatment are available for warts. Treatments are classified as either patient or clinician administered.
Molluscum Contagiosum Infection

Molluscum contagiosum (Plate 20) is a viral infection of the skin or occasionally of the mucous membranes. The typical lesion is a dome-shaped, pearly, umbilicated papule with a central curdlike core. In HIV infection, the lesions of molluscum can be large, multiple, and confluent and are often very difficult to treat. The important differentials to consider in HIV-infected patients include cryptococcosis, histoplasmosis, and penicilliosis. Toluidine blue or Giemsa staining of the white, curdlike material expressed from the lesions reveals eosinophilic molluscum bodies.

Therapy

Treatment of molluscum contagiosum can be subdivided into physician-administered and patient-administered treatments.

Patient-administered treatments include the following:
- Salicylic acid/lactic acid combination in flexible collodion (Duofilm). Duofilm provides good results, particularly in children with extensive lesions. It is applied daily to the lesions and may cause irritation.
- Salicylic acid
- Podophyllotoxin gel
- Imiquimod
- Tretinoin (0.05%) cream (to treat plane warts)

Clinician-administered treatments include the following:
- Cryotherapy
- Electrocautery
- Podophyllotoxin solution or resin
- 80% trichloroacetic acid
- Laser
- Surgical debulking of giant warts followed by topical therapy
Physician-administered treatments include the following:
- Manual extrusion of the molluscum body with gloved fingers
- Removal of the molluscum body using an orange stick
- Curettage
- Cryotherapy
- Electrocautery

Patient-administered treatments include the following:
- Benzoyl peroxide cream applied daily
- Tretinoin (0.05%) cream applied daily
- Lactic acid or salicylic acid in flexible collodion (Duofilm). Duofilm provides good results in children with molluscum contagiosum. It is applied daily to the lesions. Irritation may occur in some patients.
- Imiquimod
- Potassium hydroxide (10%) applied twice daily until either lesions undergo inflammation or ulceration results in resolution of the lesions.
- Silver nitrate
- Duct tape occlusion of the lesions has also been reported to be helpful.

**Papulonecrotic Tuberculid**

Tuberculids are skin eruptions associated with an underlying or silent form of tuberculosis. Papulonecrotic tuberculids (PNTs) present with asymptomatic papular lesions that can become pustular or necrotic (Plate 21). Lesions tend to be distributed on the extensors of the limbs. The face and earlobes may be involved. Typically, the lesions are recurrent, resolve spontaneously, and heal with scarring, only to reemerge later with lesions appearing in crops. Papulopustular secondary syphilis should be considered if the presentation is atypical. The condition can be confused with PPE; however, pruritus is not a predominant feature in PNT. A Mantoux test should be done because it is strongly positive in most patients with PNT. A skin biopsy should be also done to confirm the diagnosis of PNT. A chest X-ray is necessary to rule out the presence of pulmonary tuberculosis.

**Therapy**

The decision to treat is based on the characteristic skin lesions, a strongly positive Mantoux test, and histological confirmation of PNT. Chest X-ray is a noninvasive test that should be done in all patients with suspected PNT. Using invasive investigations of other systems to search for the mycobacterium should not be done routinely; the decision to investigate further should be guided by findings on history and physical examination.

Standard tuberculosis treatment for six to nine months should result in resolution of the lesions.

*Note: Several other dermatoses can present as papules, and a detailed discussion of them is beyond the scope of this chapter. When in doubt, a skin biopsy aids diagnosis.*

**BLISTERS**

Blisters can present as vesicles or bullae. A vesicle is a clear, fluid-filled, elevated lesion with a diameter of less than 0.5 cm. A bulla is a clear, fluid-filled lesion with a diameter of more than 0.5 cm. In HIV infection, vesicles and bullae may be the presenting cutaneous manifestation of several pathological processes, as outlined in the following algorithm.

**Varicella Zoster Infection**

Varicella zoster viral infections occur frequently in the setting of HIV infection. The patterns of presentation are usually typical, but atypical presentations can occur in HIV-infected patients. In these circumstances, diagnosis may be difficult.

Primary infection with the varicella zoster virus (VZV) presents as chicken pox (varicella; Plate
The initial lesions are vesicles associated with fever. The vesicular eruption begins on the face and extends to the trunk and extremities. In children living with HIV, primary zoster infection can be severe, with internal organ involvement causing encephalitis, pneumonitis, or pancreatitis. Other uncommon presentations of chickenpox in HIV infection include recurrent varicella (defined as recurrence of lesions at least one month after a previous episode of chickenpox) and chronic varicella (lesions that persist for more than one month). Reactivation of the latent varicella zoster virus from the dorsal root ganglia manifests as herpes zoster (shingles). The lesions present as painful vesicles and bullae in a dermatomal distribution (Plate 22b). Reactivations frequently involve the thoracic or cervical root ganglia and the ophthalmic branch of the trigeminal ganglion. Herpes zoster is common in HIV-infected patients and may present at any stage of the infection, irrespective of CD4 count.

HIV-infected patients with herpes zoster involving the ophthalmic branch of the trigeminal nerve, with or without conjunctivitis, need to be assessed by an ophthalmologist to exclude ocular involvement. Disseminated zoster is defined as lesions extending over three contiguous dermatomes or more than 20 lesions outside the initial dermatome (Plate 22c). Disseminated zoster can occur in a setting of HIV infection. Visceral dissemination, though uncommon, needs to be carefully excluded. Postherpetic neuralgia, defined as zoster pain that lasts more than one month, can occur as a complication in HIV-infected patients.

Diagnoses of varicella and zoster are made clinically, but a Tzanck smear may be useful in atypical cases.

Zoster can present as part of immune reconstitution in adult and child patients who have been initiated on antiretroviral therapy.

**Therapy**
- Acyclovir 800 mg five times a day for seven days
- Calamine lotion
- Treatment of secondary infection with appropriate antibiotics (e.g., topical mupirocin ointment applied twice daily to infected lesions)
- Pain management with analgesics

---

**Figure 6. Algorithm for the diagnosis of patients presenting with painful blisters**

- **Generalized**
  - Chickenpox (varicella zoster)
  - Drug reactions

- **Localized**
  - Oral or genital involvement
  - Dermatomal in distribution
  - Herpes simplex viral infection
  - Herpes zoster
Treatment of postherpetic neuralgia:
- Analgesics
- Amitriptyline 25 mg at night
- Neuroleptics, such as carbamazepine and lamotrigine, are useful alternatives to amitriptyline.

HIV-infected patients exposed to varicella zoster for the first time should receive VZV immunoglobulin within 96 hours of exposure.38,39

The Centers for Disease Control and Prevention (CDC) recommend VZV (live attenuated Oka strain) as a routine immunization for HIV-infected children who have no stigmata of immunosuppression.41

ULCERS

Herpes Simplex Infection1,2
In the early stages of HIV infection, the clinical presentation of herpes simplex virus (HSV) infection is similar to that seen in immunocompetent patients and is characterized by recurrent painful ulcers involving the genitalia and the perioral and perianal regions (Plates 23a–23b). Ulcers typically present as groups of vesicles that erode and heal in about two weeks.

In advanced HIV disease, the ulcers can be larger; disseminated disease is rare. Herpetic ulcers that fail to heal for longer than one month are a marker of severe immunosuppression and are considered by the CDC to be an AIDS-defining condition. It is therefore important to differentiate between these chronic herpetic ulcers and recurrent HSV infection.21,31,42 A Tzanck smear may be helpful to confirm the diagnosis of HSV.

Therapy
- Primary infection is treated with acyclovir 200 mg five times a day or 400 mg three times a day for 10 days.
- Treatment of recurrent episodes is acyclovir at a similar dosage but for 5 days.
- Valacyclovir and famciclovir can also be used when available.
- Suppressive therapy should be administered when recurrences are frequent, usually with acyclovir 400 mg twice daily.
- If lesions do not respond to acyclovir, consider using higher doses. If acyclovir resistance is suspected, intravenous foscarnet can be used.
- For alternative diagnoses, a skin biopsy for routine histology and bacterial, fungal, and mycobacterial cultures are helpful.

Cutaneous Bacterial Infection

Staphylococcus aureus1,2
S. aureus skin infections are significantly more common in the HIV-infected patient than in the immunocompetent patient. HIV-infected individuals do not have significantly different presentations, yet they tend to have more severe recurrent and atypical infections. Higher rates of chronic nasal staphylococcal carriage seen in HIV-infected patients account for the increased frequency of staphylococcal infections.43

Staphylococcal infections can present as cellulitis, furuncles (Plate 24a), ecthyma (Plate 24b), persistent and recurrent folliculitis, and impetigo. A case of staphylococcal scalded-skin syndrome in a child with AIDS has also been reported.44

Unusual infections, such as botryomycosis, can also be the presenting feature in HIV infection.18 Botryomycosis is a chronic granulomatous staphylococcal infection that presents with subcutaneous nodules, plaques, ulcers, and fistulae with purulent exudates.

Therapy
A pus swab should be sent for microscopy (Gram stain), culture, and sensitivities.
The following can be used as first-line empirical treatment:
OPPORTUNISTIC INFECTIONS, CANCERS, AND COINFECTIONS

Semisynthetic penicillins (such as cloxacillin or cephalosporins)
- In patients with methicillin-resistant *S. aureus* or patients who have penicillin allergy, oral erythromycin, clindamycin, and trimethoprim/sulfamethoxazole are useful alternatives.
- If the patient is clinically well, oral antibiotics are usually sufficient. However, if the patient is clinically toxic, intravenous antibiotics must be administered.
- The duration of treatment should be longer than normal.
- Nasal mupirocin applied three to five times a day to the nares (nostrils) should be considered in patients with recurrent staph infections.21

**Gram-Negative Bacterial Infections**

Gram-negative infections in HIV-infected patients can be problematic. *Pseudomonas* bacteremia can produce cutaneous manifestations such as ecthyma gangrenosum and otitis externa.22 A severe peri-orbital Gram-negative infection in a child with AIDS has been reported.22 This form of infection requires intravenous antibiotics to prevent septicemia and meningitis.

**CUTANEOUS MANIFESTATIONS ASSOCIATED WITH ANTIRETROVIRAL THERAPY**

Antiretroviral therapy (ART) improves the quality of life and life expectancy of HIV-infected individuals by suppressing viral replication and allowing an increase in CD4 count (i.e., immune reconstitution). Health-care providers should be on the lookout for various skin conditions that may present as a result of patient initiation on ART. Although most of these conditions are not serious, they should be promptly diagnosed and treated to ensure the patient’s comfort and continued adherence to ART.

**Immune Reconstitution Inflammatory Syndrome**

Immune reconstitution inflammatory syndrome (IRIS) is a pathologic inflammatory response to preexisting microbial, host, or other antigens that result in clinical deterioration in HIV-infected individuals after initiating ART. The following criteria for the diagnosis of IRIS have been proposed45-47:
A patient must
- be HIV-positive and receiving ART;
- have a decreasing viral load with or without an increase in CD4 count from baseline; and
- have clinical symptoms consistent with an inflammatory process in which the clinical course is not consistent with the expected course of a previously diagnosed opportunistic infection, expected course of newly diagnosed opportunistic infection, or drug toxicity.

The cutaneous manifestations of IRIS usually respond to appropriate conventional therapies. Clinicians should be familiar with the range of skin conditions associated with IRIS to avoid incorrectly diagnosing patients as having adverse cutaneous drug reactions to ART (which could lead to unnecessary discontinuation of ART). The specific features of IRIS are discussed elsewhere in this text (see chapter entitled “Immune Reconstitution Inflammatory Syndrome”).

**Nucleoside Reverse Transcriptase Inhibitors**

**Zidovudine**
Zidovudine (AZT) was one of the first antiviral agents used in the management of HIV infection. The cutaneous side effects are well documented and relate mainly to nail and mucosal hyperpigmentation. Pigmentation of the nail usually starts proximally and may manifest as complete nail pigmentation or as transverse or longitudinal bands. Pigmentation may occur on select nails or may be universal. Pigmentation also varies from blue to gray to brown, and onset is usually within one month of initiation on AZT. Discontinuation or dose reduction will result in gradual fading. Hypertrichosis (excessive growth) of body hair and eyelashes have been reported. Rare cutaneous side effects include vasculitis, exaggerated response to mosquito bites, hypersensitivity reaction, and paronychia.

**Didanosine**
Cutaneous side effects to didanosine (ddI) are uncommon. However, vasculitis and SJS have been reported. Discontinuation of ddI leads to prompt resolution and is especially important if a severe allergic drug reaction is suspected.

**Non-nucleoside Reverse Transcriptase Inhibitors**

**Lamivudine**
Lamivudine (3TC) is a relatively safe drug with few adverse cutaneous reactions. However, there have been reports of paronychia, pyogenic granuloma, alopecia, and allergic contact dermatitis caused by prolonged contact with the 3TC tablets. These are rare occurrences and do not necessitate discontinuation of the drug.

**Zalcitabine**
Ulcers of the esophagus and buccal mucosa are the most common cutaneous manifestations associated with the use of zalcitabine. Ulcers are self-limiting and resolve within a week. A transient maculopapular eruption occurs in approximately 2% of individuals, also resolving within a week. Hypersensitivity, known as DRESS (drug rash, eosinophilia, and systemic symptoms with fever and multiorgan involvement), has also been reported in isolated cases and develops within two to six weeks of therapy initiation.

**Abacavir**
Abacavir (ABC) is notorious for causing a fatal hypersensitivity syndrome that presents with fever, exfoliation, hepatitis, and eosinophilia. As soon as hypersensitivity is suspected, ABC should be discontinued, and patients should not be rechallenged; several deaths have occurred among patients rechallenged with ABC.
**Nevirapine**

The most notorious toxicities of nevirapine (NVP) are rash and hepatitis. Nevirapine-induced rash usually presents within four to six weeks of initiation as a morbilliform eruption and urticaria. The incidence of these reactions varies from 9% to 32%. However, in the absence of blisters, erythroderma, mucosal involvement, and hepatitis, therapy can be continued and the reaction treated symptomatically with antihistamines and corticosteroids. The proportion of patients requiring discontinuation is 6%–7%. SJS and TEN occur in approximately 1% of treated patients and require prompt recognition and permanent discontinuation of the drug. In these patients, reintroduction is contraindicated. The NVP lead-in period of 100 mg daily for the first two weeks and escalation to 200 mg daily thereafter aims to decrease the incidence of rash. Those at higher risk of developing NVP rash and hepatitis are females with CD4 counts greater than 250 cells/mm³ (or males with CD4 counts greater than 400 cells/mm³) and individuals with low body mass indexes. In nonpregnant females who have high CD4 counts and use reliable contraception, efavirenz is recommended as an alternative to NVP. NVP has also been implicated in the DRESS syndrome, with a 10% mortality rate from liver failure. Thus, close monitoring of patients on NVP is essential in the first eight weeks after initiation. A patient who develops a rash should always be assessed for hepatotoxicity.

**Efavirenz**

Cutaneous adverse reactions to efavirenz (EFZ) are uncommon, but patients who have reacted to NVP also have an increased risk of cutaneous drug reactions to EFZ.

**Protease Inhibitors**

Protease inhibitors (PIs) are potent agents that suppress viral load and aid in CD4 restoration. The most common cutaneous adverse reaction is lipodystrophy (LDS). Symmetrical loss of subcutaneous fat is the primary characteristic of LDS and may occur in three forms: congenital total, partial (affecting the face and lower body), and acquired total. LDS typically occurs 2 to 12 months after initiation of therapy.

Central adiposity is often associated with LDS and occurs in 6% to 64% of individuals with onset 6 to 12 months after initiating treatment with PIs, but onset may be more rapid in those taking saquinavir or ritonavir. Besides central adiposity (“crix belly” or “protease paunch”), supraclavicular deposition and buffalo hump can occur. In addition, hypertriglyceridemia, hypercholesterolemia, hyperglycemia, and insulin resistance have been reported. LDS syndromes have also been reported in those on non-PI regimens and may be related to immune restoration and HIV suppression; however, the exact mechanism is still unknown. Therapy for LDS includes surgical removal, liposuction, ketoconazole, and growth hormone. Nucleoside reverse transcriptase inhibitors, especially stavudine, have also been implicated in lipoatrophy.

Drug reactions also occur and commonly manifest as maculopapular eruptions and urticaria. Uncommonly, acute generalized exanthematous pustulosis (AGEP) can occur and presents with high fever, erythroderma, pustules, and a morbilliform eruption. AGEP should resolve without specific therapy after treatment discontinuation.

**Indinavir**

Indinavir has been implicated in a multitude of cutaneous reactions. Most commonly reported are alopecia, xerosis, lip fissuring, and paronychia. These changes are related to alterations in retinoid metabolism. Hair loss is similar to alopecia areata and occurs in the first six months of therapy. Other reactions include acute porphyria, hypersensitivity syndrome, SJS, and gynecomastia (male breast development).
**Ritonavir**
In addition to drug eruptions and hypersensitivity reactions, spontaneous bleeding is peculiar to ritonavir therapy. Increased bleeding in hemophiliacs has been reported with all PIs.

**Nelfinavir**
Nelfinavir is prescribed for children more frequently than for adults. Cutaneous side effects include maculopapular eruption and urticaria, which usually manifest 5 to 10 days after therapy initiation.

**Saquinavir**
Saquinavir is not commonly prescribed and plays a limited role in multidrug therapy. It has been reported to cause fixed drug eruptions (adverse drug reactions that recur at the same site with each administration) and gynecomastia.

**CONCLUSION**
Skin disease affects approximately 90% of individuals living with HIV.1,3,4 As immunity declines with advancing HIV infection, dermatoses become more prominent and several conditions can coexist. A thorough working knowledge of skin conditions is essential for practitioners working to effectively treat people living with HIV, thereby enhancing their quality of life.
Color Plates: Cutaneous Manifestations of HIV

Plate 1a. A case of seborrheic eczema showing weepy eczematous lesions involving the axilla.

Plate 1b. Erythematous eczematous lesions in the axilla of a child with seborrheic eczema.

Plate 1c. A child with seborrheic eczema showing greasy and yellow scales in the scalp; erythematous eczematous lesions are also present on the forehead.

Plate 1d. A case of seborrheic dermatitis showing involvement of the napkin area.
Plate 2a. A case of psoriasis demonstrating well-defined plaques with silvery white scaling

Plate 2b. Salmon pink plaques with silvery white scale on the dorsa of the hands in a patient with psoriasis

Plate 2c. Widespread plaques with silvery white scaling involving the back and buttocks in an HIV-positive patient with psoriasis
Plate 3a. A case of photodermatitis showing chronic eczematous plaques with areas of depigmentation on the scalp and posterior neck.

Plate 3b. A case of photodermatitis showing chronic eczematous plaques with depigmented areas on the extensor aspect of the upper limb in a patient.

Plate 4a. A case of tinea corporis demonstrating annular plaques that clear centrally with an active erythematous border.

Plate 4b. A case of tinea pedis showing scaling areas on the plantar aspect of the foot.
Plate 5a. A case of drug eruption demonstrating erythematous petaloid lesions involving the back.

Plate 5b. A case of erythema multiforme (EM). The individual typical lesions demonstrate the characteristic zones of EM; a central blister surrounded by a dusky erythematous zone and a pale erythematous margin. Some of the blisters have erupted leaving behind denuded skin areas, and the skin is re-epithelializing in other areas.

Plate 6a. A case of secondary syphilis demonstrating an annular plaque involving the upper limb.

Plate 6b. Papulosquamous lesions on the thigh of a patient with secondary syphilis.
Plate 6c. Annular plaques involving the “muzzle” area of the face and split papules on the angles of the mouth in patient with secondary syphilis.

Plate 6d. A case of secondary syphilis demonstrating erythematous and hyperpigmented papules on the palms of patient with secondary syphilis.

Plate 6e. Erythematous plaques on the foot of a patient with secondary syphilis.

Plate 7a. A case of prurigo showing hyperpigmented nodules on a lichenified background involving the posterior neck and upper back.
Plate 7b. A case of prurigo showing pruritic nodules on a background of lichenification involving the extensor aspect of the upper limb; the central area of the nodules is hypopigmented as a result of scratching the lesions.

Plate 8a. A case of cryptococcosis showing a large nodule on the angle of the mouth and an ulcerated nodule on lower jaw area.

Plate 8b. Ulcerative lesions in a patient with cryptococcosis.
Plate 8c. A case of cryptococcosis demonstrating multiple umbilicated papules and nodules involving the face; some of the lesions are hemorrhagic.

Plate 8d. Ulcerated nodules in a patient with cryptococcosis.

Plate 9a. A case of histoplasmosis showing gross swelling of the lips with hemorrhagic crusting and ulceration; there are crusted plaques involving the face.
Plate 9b. A case of histoplasmosis demonstrating crusted plaques involving the forearms

Plate 9c. A case of histoplasmosis demonstrating an admixture of papules and plaques involving the lower limbs

Plate 9d. Plaques and papules involving the upper limb in a patient with histoplasmosis

Plate 10a. A case of bacillary angiomatosis showing angiomatous nodules involving the posterior arm and upper back; angiomatous nodule in the center of the photograph is ulcerated

Plate 10b. A case of bacillary angiomatosis showing an angiomatous nodule
Plate 11. A blistering strongly positive Mantoux test in a patient who had erythema nodosum.

Plate 12. A case of an atypical mycobacterial infection showing crusted plaques involving the upper limb.

Plate 13. A case of Kaposi’s sarcoma showing a violaceous plaque and a nodule.

Plate 14a. A case of lymphoma showing erythematous crusted plaques involving the upper limb.

Plate 14b. A case of lymphoma showing plaques on the upper limb; there is an ulcerated crusted plaque on the lateral aspect of the forearm.
Plate 14c. Multiple nodules in a patient with lymphoma; the underlying skin is indurated and edematous giving a peau de orange appearance

Plate 16a. A case of scabies showing pruritic papules and scabetic burrows involving the toe web spaces

Plate 16b. A case of Norwegian (crusted) scabies demonstrating crusted plaques on the wrist and dorsa of hand; note the involvement of the web space

Plate 15. Whitish plaques on the tongue of a patient with oral candidiasis
Plate 17a. Erythematous pruritic papules involving the face, with ear lobe involvement in a patient with papulopruritic eruption of HIV

Plate 17b. A case of papulopruritic eruption demonstrating erythematous papules involving the face
Plate 18a. A case of papular urticaria demonstrating excoriated erythematosus papules predominantly involving the upper limbs

Plate 18b. A child with papular urticaria showing erythematous pruritic papules on the forearm (exposed site); a linear distribution of the lesions is apparent

Plate 19a. Multiple filiform warts involving the genital area in an immunocompromised child

Plate 19b. A case of extensive plane warts showing multiple plane topped hypopigmented papules involving the chest, abdomen, and upper limbs
Plate 20. Dome-shaped, pearly, umbilicated papules involving the neck and anterior chest in a child with molluscum contagiosum; larger (giant) molluscum lesions are also present.

Plate 21. A case of papulonecrotic tuberculid showing papular lesions with necrotic centers involving an upper limb extensor.

Plate 22a. Vesicular lesions on an erythematous background involving the shoulder region in a patient with varicella zoster (chicken pox).

Plate 22b. A case of herpes zoster showing grouped vesicles and bullae in a dermatomal distribution.
Plate 22c. Involvement of more than one dermatome in an immunocompromised patient with multidermatomal herpes zoster; erythematous vesicles, crusts, and erosions involving the V3, C3, and C4 dermatomes are shown.

Plate 23a. A case of genital herpes demonstrating multiple punched-out ulcers involving both labia.

Plate 23b. A large painful ulcer with an erythematous base involving the angle of the mouth in an immunocompromised child with chronic herpes.
Plate 24a. A case of furunculosis, some of the furuncles have coalesced to form carbuncles

Plate 24b. A case of ecthyma from a staphylococcal infection showing crusted ulcerative lesions involving the leg; the lesions tend to heal with scarring

HEPATITIS B VIRUS (HBV) INFECTION poses a significant global public health threat, especially in vulnerable populations, such as people living with HIV infection. Approximately two billion people worldwide have serological evidence of HBV infection, and more than 350 million have chronic infection, defined as detection of hepatitis B surface antigen (HBsAg) for more than six months following acute infection (Figure 1). In China, home to 75% of the world’s chronic HBsAg carriers, chronic infection with HBV is the leading cause of both cirrhosis and hepatocellular carcinoma (HCC). Transmission of HBV occurs through percutaneous and mucosal exposure (usually sexual) to blood or body fluids contaminated with blood. HBV is present in most bodily fluids, including blood, semen, and saliva. Studies have demonstrated that HBV is infectious via both semen and saliva, and that HBV DNA is present in urine as well.

EPIDEMIOLOGY OF HBV

The epidemiology and natural history of HBV infection vary significantly by world region. The United States and Western Europe typically have lower prevalence rates, estimated at 5% to 7% with serological evidence of prior exposure and less than 1% with chronic infection. In areas with low hepatitis B prevalence rates, such as the United States, sexual transmission accounts for the majority of disease with onset of disease usually in adolescence and young adulthood. In parts of Asia and sub-Saharan Africa, where hepatitis B is endemic, exposure and acquisition typically occur perinatally or in very early childhood; more than 70% of people in these regions have antibody markers indicative of prior infection.

Areas of moderate HBV prevalence include Eastern Europe, parts of the Middle East, northern Africa, and parts of South America. In these regions, the prevalence of chronic HBV infection ranges from 2% to 7%, with evidence of prior exposure in up to 60%. Risk and infection routes vary by subpopulation—infection may spread through perinatal or early childhood exposure, injection drug use, or sexual transmission.

In East Asia, perinatal transmission is common. In China, it has been estimated that 35% to 50% of chronic hepatitis B infection is due to perinatal transmission. In contrast, infection in sub-Saharan Africa is attributable mainly to horizontal early childhood transmission, occurring before the age of five. Exposure is thought to be mediated by medical procedures, close household contact,
traditional scarification, and other unidentified mechanisms.\textsuperscript{6,11-13} Hepatitis B e antigen (HBeAg) prevalence is low in these regions, raising the speculation of a lower risk of vertical transmission.\textsuperscript{14} For example, in Zimbabwe, HBeAg was present in 5% to 15% of HBsAg-positive carriers.\textsuperscript{14}

**GLOBAL EPIDEMIOLOGY OF HIV AND HBV COINFECTION**

HIV-HBV coinfection is common because of shared routes of transmission; both are spread through parenteral and sexual contact. In North America and Europe, prevalence of chronic HBV infection is higher in HIV-positive populations than among those who are HIV-negative, with rates ranging from 4% to 10%.\textsuperscript{15-17} In Africa and Asia, however, most studies suggest that the prevalence of chronic HBV infection does not differ between HIV-positive and negative populations.\textsuperscript{18-22} Notable exceptions come from data in China and Nigeria, where HBV infection was found to be higher in HIV-positive populations.\textsuperscript{23-24} The reasons for these differences are unclear but may be related to other shared risk factors (such as injection drug use in the Chinese study).

**NATURAL HISTORY OF HBV INFECTION**

The risk of chronic HBV infection is highest with earlier age of infection.\textsuperscript{25} Chronic HBV infection occurs in 90% of infants with perinatal infection,\textsuperscript{25} 30% of children who are exposed to HBV before the age of five,\textsuperscript{26} and 2% of immunocompetent adults.\textsuperscript{25} The natural history of chronic HBV infection can be divided into five phases: immune tolerance, HBeAg-positive chronic hepatitis B, the inactive HBSAg carrier state, HBeAg-negative chronic hepatitis B, and recovery (Table 1).\textsuperscript{27} An interpretation of serologic markers is provided in Table 2. These stages are based on immune status, HBV DNA levels, presence of HBeAg, and alanine aminotransferase (ALT) levels.\textsuperscript{28-29}

The immune tolerance phase, which predominates through early adulthood in perinatally acquired disease, is marked by the presence of HBeAg, high levels of HBV DNA, normal ALT levels, and little histological activity on biopsy.29-30 During HBeAg-positive chronic hepatitis B, fluctuating ALT levels (or flares) are common and are thought to represent the immune-mediated destruction of infected hepatocytes. Progression to cirrhosis and HCC are thought to be related to the frequency and severity of flares as well as the duration of the immune clearance phase.31-32 In the majority of patients, chronic HBeAg-positive disease transitions to the inactive carrier state,33 characterized by seroconversion to hepatitis B e antibody (anti-HBe), persistent HBsAg, and low or undetectable serum HBV DNA.34-36 Seroconversion in those with elevated ALT levels occurs at a rate of 8% to 12% per year.31,34-37,38 Reactivation of the inactive carrier state can also occur spontaneously or through immune suppression.33,39-40

In up to one-third of patients, chronic HBeAg-positive disease transitions to chronic HBeAg-negative disease.41 In this variant form of disease, mutations in the core promoter and precore domains result in diminished or absent HBeAg production, but HBV DNA levels remain high and ALT levels fluctuate.42 Individuals with HBeAg-negative disease have higher relapse rates after treatment cessation, and rates of sustained treatment response are poor.43-45

Occult HBV infection, an additional stage and one that may overlap with the recovery stage,46 is defined as low-level HBV DNA in the absence of detectable HBsAg.47-48 With occult HBV infection, anti-HBc (IgG) may be the only marker present. The isolated anti-HBc may represent a false-positive antibody result, a “window” phase of acute
increased levels of HBV DNA, a higher proportion of HBeAg positivity, a lower likelihood of seroconversion to anti-HBe and antibody to HBsAg (anti-HBs), and a higher prevalence of occult HBV in some, but not all, studies. Notably, ALT levels are not always elevated with chronic hepatitis B, despite progression to cirrhosis.

In those with chronic hepatitis B, coinfection with HIV results in an increased rate of progression to death, cirrhosis, and HCC. An analysis of the U.S. Multicenter AIDS Cohort Study found that liver-related mortality was approximately 14 times higher with HBV/HIV coinfection than with either HBV monoinfection or HIV monoinfection. In HIV-positive individuals, progression of acute to chronic HBV infection occurs at a rate five times higher than in HIV-negative individuals. In another French study, HCC was the cause of

*Chronic infection with HBeAg (+) and anti-HBe (−) is the pattern with wild-type virus, whereas HBeAg (−) and anti-HBe (+) is the pattern with precore or basal core promoter virus.

Abbreviations: HBV = hepatitis B virus; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; anti-HBs = antibody against HBV surface antigen; anti-HBc = antibody against HBV core antigen; anti-HBe = antibody against HBV e antigen; IgM = immunoglobulin M.

infection (if IgM antibody positive), recovery from acute hepatitis B but without the development of or loss of anti-HBs, or true occult infection. Occult HBV has been associated with HBV reactivation, diminished treatment response to interferon in HCV-coinfected individuals (according to some publications), and development of HCC. Occult HBV infection has also been associated with HBV transmission through blood donation and liver transplantation.

Impact of HIV on the Natural History of HBV Infection
HIV modifies HBV disease in many ways. Most importantly, HIV infection results in an increased incidence of death and cirrhosis in those with hepatitis B infection. HIV infection also results in an increased risk of developing chronic hepatitis B,
liver-related death in 50% of HIV/HBV-coinfected individuals, a proportion higher than in HIV/HCV coinfection or HIV disease alone.\(^6^0\)

In the era prior to antiretroviral therapy (ART), having HIV increased the risk of both contracting HBV\(^6^1-^6^4\) and becoming a chronic HBsAg carrier,\(^5^9\) although chronic carrier likelihood may differ in areas of high versus low HBV prevalence.\(^4^4\) In addition, studies from the United States and Europe demonstrated that HBV viremia was higher in those with HIV coinfection and that the loss of HBeAg occurred at a slower rate.\(^6^3,^6^5-^6^7\)

Similar results were seen in Africa. In Côte D’Ivoire, HIV/HBV-coinfected pregnant women were more likely to have HBV viremia (27%) than those with HBV infection alone (9%).\(^1^9\) In Zambia, HBeAg was more prevalent during HIV infection.\(^5^8\) As the presence of HBeAg and elevated HBV DNA levels are associated with an increased risk of HBV transmission, these results may indicate that HIV- and HBV-coinfected individuals may be at higher risk for HBV transmission.

Occult HBV infection, defined as either the prevalence of anti-HBc alone or HBV DNA in the absence of HBsAg, is greater in HIV-positive individuals than in those who are HIV-negative.\(^6^9-^7^2\) Prevalence estimates in several HIV-positive cohorts vary widely, ranging from 0% to 54%.\(^6^9,^7^3-^7^7\) These differences are likely related to the sensitivity of the assays. Paradoxically, a study from South Africa reported a higher prevalence of the “anti-HBc alone” marker pattern in HIV-negative versus HIV-positive patients.\(^7^8\)

The clinical relevance of occult HBV in HIV disease has yet to be determined. In the Swiss HIV cohort, Hofer et al. detected elevated liver enzymes in pre-ART patients with occult HBV infection regardless of HCV serostatus.\(^6^9\) Another recent prospective study detected a significantly higher rate of liver enzyme elevations in HIV-positive patients with occult HBV than in those without HBV DNA.\(^7^9\) These patients experienced hepatic flares upon immune reconstitution with lamivudine-containing ART. In contrast, French investigators have reported prospective follow-up of HIV-positive patients with anti-HBc alone that included four occult infections with no evidence of liver enzyme elevations.\(^8^0\) In summary, occult HBV is prevalent in HIV infection and, in those without HIV disease, has been implicated in several types of adverse clinical outcomes, but its long-term clinical relevance deserves further study.

Finally, ALT levels are often not significantly elevated in HBV/HIV coinfection. One pre-ART analysis in HIV-positive patients concluded that although HIV-positive patients were more likely to be HBeAg-positive and HBV DNA-positive than those without HIV, liver enzyme elevations were significantly less elevated in those with HIV infection.\(^5^9\) Furthermore, ALT was positively correlated with CD4 count in this study, suggesting that liver inflammation is dependent on immune function preservation even within the setting of HIV.

ART-Associated Hepatotoxicity
Another effect of HBV on HIV is the increased risk of hepatotoxicity during treatment with antiretroviral therapy. Nearly 10% of subjects initiating ART will experience significant aminotransferase flares.\(^8^1\) Coinfection with HBV increases the risk of hepatotoxicity after initiation of ART.\(^8^2-^8^4\) A study in Thailand in which nearly 8% of the 692 HIV-positive patients were HBV coinfected found that the incidence of severe hepatotoxicity for those with HBV was 15.3/1,000 person-years—greater than twice the overall incidence. HBV was a significant predictor of hepatotoxicity with an adjusted relative risk of 3.2.\(^8^5\)

The mechanisms underlying hepatotoxicity remain unclear. ART-associated hepatotoxicity may be mediated through mitochondrial toxicity,\(^8^6\) hypersensitivity reactions (such as with nevirapine
and abacavir), direct liver injury from antiretroviral agents, or HBV immune reconstitution. Additionally, the concomitant administration of other hepatotoxic medications, such as antituberculous agents, may also play a role.

In HIV disease, the immune reconstitution syndrome occurs when ART-induced immune recovery results in immune activity against antigens from resolved or ongoing infection. HBV-associated immune reconstitution has been reported and has been associated with clearance of both HBeAg and HBsAg. Importantly, immune reconstitution hepatitis has been reported even during lamivudine therapy.

Finally, the concomitant administration of other hepatotoxic drugs with ART, such as antituberculous therapy, has special implications for areas endemic for HIV, HBV, and TB. In one South African study, HBV infection increased the risk of hepatotoxicity in those receiving antituberculous therapy and ART.

Other Causes of Aminotransferase Elevation in HIV/HBV Coinfection
When evaluating the HIV/HBV-coinfected patient with elevated aminotransaminases, other important etiologies should also be considered. The differential diagnosis includes the hepatic flares associated with the natural immune clearance of hepatitis B; rebound viremia from either the inadvertent withdrawal of anti-HBV therapy or HBV resistance; and other etiologies such as alcohol abuse, coinfection with other hepatitis viruses (A, C, D, or E), and other opportunistic infections and malignancies.

HBV PATHOGENESIS AND GENETIC VARIANTS
The hepatitis B virus is a small, 3,200 kilobases (kb), hepatotropic DNA virus. The partially double-stranded circular DNA encodes four overlapping open reading frames: S for the surface gene, C for the core gene, P for the polymerase gene, and X for the X gene. The S gene encodes the viral envelope. The core gene produces the e antigen protein (HBeAg). The HBV virus enters liver cells (hepatocytes) and, after entry, is transported to the cell nucleus, establishing a persistent reservoir as covalently closed circular DNA (cccDNA) in the host hepatocyte. This cccDNA then acts as the stable template for viral protein translation and reverse transcription into genomic DNA (see Figure 2).

Hepatitis B-associated liver injury is immune mediated; the hepatitis B virus is itself noncytopathic. The pathogenesis of liver damage is related to B and T cell immune response to peptide antigens, production of cytopathic and noncytopathic cytokines, and the recruitment of nonspecific effector leukocytes.

Hepatitis B Genotypes
There are eight HBV genotypes (A–H), with a divergence of greater than 8% in the entire genomic sequence. The eight genotypes have a geographical distribution: A is prevalent in northwestern Europe, North America, and Africa; B and C are endemic in Asia; D predominates in the Mediterranean but has a worldwide distribution; E is found in West Africa; F is found in the aboriginal populations in South America; and G has been found only in France and the United States. In South Africa, HBV genotypes A and D can be further divided into subgenotypes A1 and A2, and D1–D3.

Genotypes are predictive of natural history progression. Genotypes B, C, and D are associated with the development of core and precore promoter mutations. Studies from Japan, Taiwan, and China indicate that genotype C, when compared with genotype B, is associated with more severe liver disease. In India, where genotypes
infection can be divided into HBeAg-positive and HBeAg-negative disease. Patients with HBeAg-negative disease do not express HBeAg because of mutations in the precore and core regions of the HBV genome.119-120

HBeAg-negative disease, defined as the absence of HBeAg production but with active HBV replication, is not thought to arise de novo but rather as the evolution of chronic HBV infection. HBeAg-negative disease is associated with a poorer long-term prognosis, and sustained spontaneous remission is rare. The precore and core promoter mutations are also associated with genotypes B, C, and D. It is not known whether there is an increased proportion of HBeAg-negative disease in HIV infection.

Precore and Core Promoter Mutations
HBeAg is generally regarded as a marker of HBV replication. A subset of patients with HBV infection have high levels of HBV replication in the absence of HBeAg production. Thus, chronic HBV infection can be divided into HBeAg-positive and HBeAg-negative disease. Patients with HBeAg-negative disease do not express HBeAg because of mutations in the precore and core regions of the HBV genome.119-120

HBeAg-negative disease, defined as the absence of HBeAg production but with active HBV replication, is not thought to arise de novo but rather as the evolution of chronic HBV infection. HBeAg-negative disease is associated with a poorer long-term prognosis, and sustained spontaneous remission is rare. The precore and core promoter mutations are also associated with genotypes B, C, and D. It is not known whether there is an increased proportion of HBeAg-negative disease in HIV infection.
MANAGEMENT OF HEPATITIS B IN THE SETTING OF HIV INFECTION

Goals, Predictors, and Duration of Therapy
The goals of hepatitis B therapy in HIV/HBV coinfection are similar to those in HBV monoinfection: to suppress HBV viral replication, promote HBeAg seroconversion (in those with HBeAg), and, ultimately, decrease the progression to cirrhosis and/or HCC. Loss or decrease in HBV DNA is considered an acceptable surrogate marker for successful HBV treatment. In HIV infection, an additional benefit of treatment of HBV infection may include the possibility of decreasing ART-associated hepatotoxicity.

In HBV monoinfection, the predictors of a favorable treatment response include low pretreatment HBV DNA levels, the presence of HBeAg, and evidence of liver inflammation demonstrated by liver biopsy or elevations in liver enzymes. The predictors of optimal treatment response in HIV and HBV coinfection are unknown.

The optimal duration of therapy for chronic hepatitis B in HIV infection is also unknown, but given the suppressive nature of therapy and the concomitant treatment of HIV with anti-HBV active therapy, the duration of therapy will likely be lifelong. Several studies have shown that markers of liver damage may improve with successful therapy in some patients. For example, Matthews et al. found that after approximately two years of treatment with tenofovir in cirrhotic HBV-HIV-infected patients, all markers of liver injury improved. Another study assessed improvement in liver damage with tenofovir therapy via biopsy, and yielded similar results.

Anti-HBV Therapy
Several agents are currently available for the treatment of chronic hepatitis B: lamivudine, adefovir, tenofovir, emtricitabine, entecavir, telbivudine, and interferon. Tenofovir and emtricitabine are not officially approved for hepatitis B infection but have been studied in its treatment. In resource-limited settings, as of this writing, lamivudine will likely be the most accessible agent, although tenofovir may be more widely available soon. Lamivudine, tenofovir, and adefovir are discussed in the following paragraphs.

Lamivudine, a nucleoside analogue, is currently the most widely available drug for hepatitis B in low-income settings. The dosage for chronic hepatitis B therapy is 100 mg daily, but the dosage in HIV infection, 300 mg daily, is the appropriate dosage if both HIV and HBV are to be treated. In HIV/HBV-coinfected patients, lamivudine monotherapy is associated with HBV DNA reductions to below 10^5 copies/mL in 40% to 87% of patients. A major limitation to single-agent lamivudine therapy for hepatitis B is the development of HBV lamivudine resistance (see the following subsection).

Although not formally approved for the treatment of hepatitis B, tenofovir disoproxil fumarate, a nucleotide analogue also used in the treatment of HIV, has been widely used and studied in HIV/HBV coinfection. Studies in high-income countries have demonstrated its activity against HBV in lamivudine-naive and lamivudine-resistant HIV/HBV-coinfected patients. Tenofovir may also become more accessible in resource-limited settings; tenofovir and coformulated tenofovir and emtricitabine were approved in South Africa in April 2007. In 54 HIV/HBV-coinfected individuals with HBeAg-positive chronic hepatitis B, tenofovir produced a median reduction in HBV DNA of 4.56 log_{10} copies/mL and 30% achieved an undetectable HBV viral load. In 11 treatment-naive and -experienced HIV/HBV-coinfected patients, tenofovir was effective in suppressing HBV replication.
Adefovir, a nucleotide analogue approved for the treatment of chronic hepatitis B, does not have known anti-HIV activity at the anti-HBV active dose of 10 mg daily. In lamivudine-resistant HIV/HBV-coinfected patients, the addition of adefovir resulted in sustained and significant reduction in HBV DNA levels.141

**Hepatitis B Drug Resistance**

When lamivudine is used as monotherapy for the treatment of HBV in the setting of HIV infection, lamivudine resistance approaches 100% at four years. Lamivudine resistance occurs when point mutations alter the highly conserved YMDD motif in the C domain of the HBV polymerase gene, preventing lamivudine binding. Lamivudine resistance is accompanied by rebound viremia, ALT elevation, and reversal of histologic improvement. In HIV/HBV coinfection and cirrhosis, HBV drug resistance can lead to fulminant hepatitis. In medication-compliant patients who experience a greater than 1 log10 copies/mL increase in serum HBV DNA from nadir, lamivudine resistance should be considered. The optimal treatment for lamivudine-resistant HIV/HBV-coinfected individuals is not well defined. Most experts recommend the addition rather than the replacement of a second anti-HBV agent. Both tenofovir and adefovir exhibit activity against lamivudine-resistant virus in HIV infection. Entecavir should be used with caution as background lamivudine resistance mutations facilitate entecavir resistance.

**Approach to the Management of HIV/HBV Coinfection in Resource-Limited Settings**

Because of resource limitations, including limitations in drug availability, the management of hepatitis B infection in resource-limited settings will differ from that in high-income settings. References for HBV treatment in high-income countries are listed here. As of this writing, there are no data on HBV management in HIV infection in resource-limited settings. The following are our recommendations, modified from previously published recommendations in resource-limited settings, but not yet proven through rigorous clinical trials.

HBsAg and transaminase testing should be available at the clinic level, both at the initiation and, in the case of transaminases, at follow-up evaluations. Additional follow-up laboratory tests such as HBeAg, anti-HBe, and HBV viral load could be reserved for district-level testing.

In HBV-endemic areas, we advocate screening for HBsAg and liver enzymes at primary health care centers and before the initiation of ART. Individuals with HIV/HBV coinfection should be asked about symptoms of severe liver disease, including hematemesis, hematochezia, and abdominal and leg swelling. Alcohol intake and family history of HCC should also be queried. Examination should include the evaluation of severe liver disease including jaundice, ascites, spider angioma, lower extremity edema, and palmar erythema. If available, HBeAg, anti-HBe, HBV DNA, prothrombin time, albumin, and a complete blood count should be obtained.

If HBsAg screening is not available, a reasonable, but unstudied, alternative may be to initiate ART therapy, monitoring for signs and symptoms of hepatotoxicity (i.e., abdominal pain, jaundice, scleritis). Should these symptoms develop, a history designed to exclude other causes of hepatotoxicity should be obtained, and subsequent laboratory evaluation should include ALT and hepatitis A and B serologies. The non-hepatitis differential diagnosis includes antiretroviral-related hepatotoxicity (with nevirapine being the usual agent), AIDS-related opportunistic infections that target the liver, lactic acidosis (with hepatic steatosis if stavudine or didanosine are included in the regimen), and hepatotoxicity from...
other medications (i.e., anti-TB medications). Hepatitis-related etiologies include acute infection with hepatitis A, B, or C, and, in the setting of HBsAg-positive disease, hepatitis B immune reconstitution and hepatic flares. If serologies demonstrate HBsAg positivity, then the addition of a second anti-HBV active drug (in most settings, tenofovir) should be considered.

When to Initiate Therapy
HBV therapy should be commenced concurrently with ART.

Management of HBV Disease in Patients on ART
If available, ART for coinfected patients should include two anti-HBV active agents. In the setting of HIV/HBV coinfection, combination nucleoside therapy is associated with more potent HBV suppression, and may be associated with the reduced incidence of drug resistance, although this protection against resistance has not been definitively established. If tenofovir is available, then we recommend combination therapy with tenofovir and lamivudine or emtricitabine. Coformulated tenofovir and emtricitabine, although not approved in the United States for the treatment of chronic hepatitis B, has also been used and retrospectively studied for the treatment of HIV and HBV coinfection. To maintain HBV suppression, anti-HBV therapy should be continued indefinitely.

Nevirapine should be avoided, because of the higher rates of hepatotoxicity in HIV/HBV coinfection. Additionally, use of didanosine and stavudine, individually or in combination, should be avoided if possible. Finally, lamivudine and emtricitabine should not be used concomitantly, as both share a similar mechanism of action.

If, at the time of HBsAg identification, HIV therapy has already been initiated and does not contain two anti-HBV active drugs, the optimal approach would include the addition of a second anti-HBV agent.

If a second-line ART regimen is necessary (i.e., due to toxicity, treatment failure, etc.), continuation with a regimen that contains an anti-HBV agent (e.g., lamivudine, tenofovir, emtricitabine) is recommended. If anti-HBe testing is available, this test should be performed every six months to a year. If anti-HBe seroconversion has occurred, then anti-HBV therapy may be discontinued six months after anti-HBe seroconversion. If anti-HBe testing is not available, then an HBV-active agent should be continued for the duration of ART. Early discontinuation of anti-HBV therapy can lead to rebound HBV viremia, elevated aminotransferase levels, and, in some immunosuppressed patients, hepatic failure.

Monitoring During Treatment
In HIV-positive and HBsAg-positive patients, liver enzymes should be evaluated at least once or twice in the first three months after ART initiation. If available, serum HBV DNA, HBeAg, and anti-HBe should be measured every six months. If lamivudine or emtricitabine is the only HBV-active drug in the regimen (i.e., HBV monotherapy), a rise in liver enzymes or HBV DNA should prompt the consideration of HBV drug resistance. Additional considerations include antiretroviral-related hepatotoxicity (nevirapine, efavirenz, stavudine, didanosine), concomitant hepatotoxic medications (i.e., anti-TB), other hepatotropic opportunistic infections, immune reconstitution/HBV flare, acute hepatitis from A/C/D/E, and/or alcohol abuse.

The optimal strategy to manage HBV drug resistance in HIV infection is unknown; in the setting of lamivudine resistance, most consensus panels recommend the addition of tenofovir.

In high-income countries, screening for HCC with biannual alpha-fetoprotein measures and liver ultrasounds is recommended.
Prevention of Further Liver Damage

Even without treatment, steps may be taken to prolong time to severe liver injury. Alcohol interacts synergistically with viral hepatitis to exert injurious effects on the liver. There are several mechanisms by which this may occur, including increased lipid peroxidation, less hepatocyte regeneration, alteration of key metabolic pathways, and reduced DNA repair capacity.149 Alcohol avoidance, while not necessarily reversing damage already incurred, will serve to soften the effects of viral hepatitis and drug interactions on an already compromised liver.

In addition, individuals with HBV infection who have not been exposed to hepatitis A should receive the hepatitis A vaccine.156 Acute infection with hepatitis A in hepatitis B-coinfected individuals can result in fulminant hepatitis.150

PREVENTION OF HEPATITIS B

Hepatitis B can be prevented through vaccination (children and adults) and through administration of hepatitis B immune globulin and vaccination (neonates).

Prevention of HBV Perinatal Transmission

In infants and children, the two major routes of HBV acquisition are via perinatal and horizontal transmission. In pregnant women who are HBsAg- and HBeAg-positive and who do not receive immunoprophylaxis, a newborn's risk for chronic HBV infection at six months is 70% to 90%.151-155 Infants born to mothers who are HBeAg-negative have a less than 10% risk of developing chronic hepatitis B. Predictors of HBV transmission include the presence of HBeAg and high-level HBV viremia.154 Breastfeeding in HBsAg-positive mothers is not thought to increase the risk of HBV acquisition.155

The current HBV perinatal exposure prophylaxis regimen in high-income countries includes the administration of hepatitis B immune globulin (HBIG) and HBV vaccine, both administered within 12 to 24 hours of birth, followed by the completion of the HBV vaccination series. This regimen is 85% to 95% effective in preventing chronic HBV infection in infants born to women with both HBsAg and HBeAg.156

In low-income countries where HBIG administration may be limited by cost and cold-storage availability, World Health Organization (WHO) recommendations note that hepatitis B vaccination alone, if administered within 24 hours of birth, is comparable to the combination of hepatitis B vaccination and HBIG administration in the prevention of mother-to-child transmission of hepatitis B.156

The use of nucleos(t)ide therapies as an alternative to HBIG and the HBV vaccination has been raised.97 To date, only two small studies have examined the administration of lamivudine to HBsAg-positive mothers in order to prevent HBV transmission to the infant.157-158 Both have suggested that lamivudine may be effective in reducing HBV transmission, but larger studies are needed, especially in HIV-coinfected women, where HBV viral loads may be higher than in their monoinfected counterparts.

Routine Hepatitis B Vaccination

Neonates and Children

In 1991, WHO called for routine global infant and childhood HBV immunization, initially targeting regions and countries with high HBV prevalence.1 Hepatitis B immunization strategies include routine infant vaccination, prevention of perinatal HBV transmission, and catch-up vaccination of older age groups.159

Routine infant HBV vaccination is encouraged in low-, intermediate-, and high-endemicity HBV countries, with the timing of vaccination differing between regions with varying endemicities. HBV vaccination at birth (provision of birth dose) in order to prevent perinatal HBV transmission
In HIV-positive individuals with well-preserved CD4 counts (defined as greater than or equal to 500 cells/mm³), a normal HBV vaccine dosing schedule is recommended. In those with evidence of immunosuppression, a more intensive schedule is suggested (20 µg at months 0, 1, 2, and 12). Those who do not respond to the first vaccination cycle should receive booster doses or undergo a second cycle with a double-dose regimen until titers greater than or equal to 100 IU/L are observed.\textsuperscript{126}

CONCLUSION
In summary, HIV/HBV coinfection is a common occurrence. HIV alters the natural history of hepatitis B disease, resulting in increased HBV viremia, increased HBV drug resistance, and increased mortality when compared to HBV infection alone. If possible, ART in HIV/HBV-coinfected patients should include two HBV-active agents. When lamivudine is the only HBV-active agent, lamivudine resistance occurs in the majority of HIV/HBV-coinfected patients on lamivudine-containing ART.

Prevention and Management of Malaria Infection in People Living with HIV

Paula E. Brentlinger and Christopher B. Behrens

Human malaria infection is usually caused by four parasites: Plasmodium falciparum, P. ovale, P. malariae, and P. vivax. The most common of the four are P. vivax and P. falciparum, with P. falciparum being the most lethal. In some regions of the world, a single parasite species predominates (e.g., P. vivax in Central America and P. falciparum in sub-Saharan Africa); in other regions, the geographic distributions of two or more species may overlap substantially. The global burden of malaria is immense. Snow et al, in an estimate that attempted to correct for deficiencies in case reporting, concluded that in 2002 alone, there were 513 million episodes (range: 300–660 million) of symptomatic P. falciparum malaria. Snow et al further estimated that 2.2 billion people were at risk of P. falciparum malaria, and that attack rates in the most highly endemic regions were 849 cases per 1,000 population per year. The distribution of malaria overlaps that of HIV-1 infection broadly, especially in sub-Saharan Africa.

Interactions between Malaria and HIV
Interactions involving P. falciparum and HIV have resulted in increases in the burden of both diseases. Reported interactions that are of interest to clinicians fall into the following broad categories:

1. Increases in HIV replication rate and/or viral load in the presence of acute malaria
2. Reversible decline in CD4 T-lymphocyte count in the presence of acute malaria
3. Increased incidence, prevalence, and severity of malaria in HIV-positive individuals (especially in pregnancy, where adverse consequences may affect both mother and fetus)
4. Increased likelihood of malaria treatment failure in HIV-positive individuals

Recent research on interactions between the malaria parasite, the human immune system, and HIV itself has begun to describe plausible mechanisms for some of the observed interactions. The existing data (which are restricted to interactions between HIV and malaria caused by P. falciparum, owing to lack of available data regarding other Plasmodium species) are summarized in Table 1. Similar interactions are likely to exist between HIV and the other Plasmodium species, but published studies do not yet describe them.

From the Ground Up: Establishing a Framework for Success

Parasitemia are largely related to steadily worsening anemia. However, asymptomatic parasitemia has been observed to confer a fivefold elevation in the risk of symptomatic malaria in young children.28

Asymptomatic Placental or Maternal Peripheral Parasitemia
Asymptomatic malaria parasitemia (P. falciparum and/or others) has been noted in 10%–70% of pregnant women living in regions of stable malaria transmission.20,29 It is associated with maternal anemia, maternal mortality, and infant low birth weight.29 In a recent autopsy study of maternal mortality in Mozambique, evidence of recent or current malaria infection was detected in 66.2% of maternal deaths, though only 10.1% of deaths were thought to have been caused directly by severe malaria.30 Maternal malaria infection has recently been associated with reduced transfer of maternal tetanus antibodies to the fetus.31 Vertical transmission of HIV may be increased in the presence of maternal malaria, and placental malaria conferred a relative risk of 7.9 for vertical transmission in one study (although this finding has not been consistently replicated).32,33 There is also evidence of association between maternal malaria and eclampsia.34,35

Latent Infection
The life cycles of P. vivax and P. ovale include a liver-stage parasite known as a hypnozoite. If left untreated (the standard therapy is primaquine), latent infection may cause relapses of symptomatic malaria weeks to years after initial infection.25

Asymptomatic Parasitemia
Asymptomatic parasitemia is generally the consequence of P. falciparum infection in older children and adults living in regions of stable transmission. Morbidity and mortality in asymptomatic parasitemia are largely related to steadily worsening anemia. However, asymptomatic parasitemia has been observed to confer a fivefold elevation in the risk of symptomatic malaria in young children.28

Asymptomatic Placental or Maternal Peripheral Parasitemia
Asymptomatic malaria parasitemia (P. falciparum and/or others) has been noted in 10%–70% of pregnant women living in regions of stable malaria transmission.20,29 It is associated with maternal anemia, maternal mortality, and infant low birth weight.29 In a recent autopsy study of maternal mortality in Mozambique, evidence of recent or current malaria infection was detected in 66.2% of maternal deaths, though only 10.1% of deaths were thought to have been caused directly by severe malaria.30 Maternal malaria infection has recently been associated with reduced transfer of maternal tetanus antibodies to the fetus.31 Vertical transmission of HIV may be increased in the presence of maternal malaria, and placental malaria conferred a relative risk of 7.9 for vertical transmission in one study (although this finding has not been consistently replicated).32,33 There is also evidence of association between maternal malaria and eclampsia.34,35

Latent Infection
The life cycles of P. vivax and P. ovale include a liver-stage parasite known as a hypnozoite. If left untreated (the standard therapy is primaquine), latent infection may cause relapses of symptomatic malaria weeks to years after initial infection.25

Signs and Symptoms of Acute Uncomplicated Malaria, and Their Occurrence in Other HIV-Related Conditions
Malaria represents a daunting diagnostic challenge in the HIV-positive patient.36 Its clinical symptoms overlap with those of opportunistic infections (OIs),
adverse drug reactions (ADRs), immune reconstitution inflammatory syndrome (IRIS), other infectious entities that are common in resource-limited environments, and advanced AIDS itself. To further complicate matters, asymptomatic malaria parasitemia may coexist with OIs (and other disease entities) that share symptoms with malaria. Common signs and symptoms of malaria, with important considerations in differential diagnosis, are described below.

**Fever**

Fever without apparent source is a common clinical problem in HIV-positive persons; its observed incidence was 602.5 events per 1,000 person-years of observation in one adult cohort in Nairobi, Kenya. Most clinicians in malaria-endemic settings are quick to suspect malaria in the febrile patient. However, TB, cryptococcosis, bacteremia, typhoid fever, dengue, influenza, and various other entities (including ADRs and IRIS) may present in a similar fashion. More than one cause of fever may be present concurrently in the HIV-positive patient. Several groups of investigators have attempted to characterize the causes of fever in HIV-positive adults and children; the findings of selected studies are summarized in Table 2.

presentation of malaria may easily be confused with that of an upper respiratory infection, bronchitis, pneumonia, or other conditions. Malaria and bacterial pneumonia may be clinically indistinguishable (especially in children) and may even occur simultaneously; concurrent infections have been described both in children and in HIV-positive adults.42,46-48

Vomiting and/or Diarrhea
Gastrointestinal symptoms are common in acute malaria, and may be confused with gastroenteritis (multiple opportunistic and other etiologies) or ADRs.

Nonspecific Complaints
Particularly in young children and infants, the signs and symptoms of malaria may include such
nonspecific complaints as lethargy, irritability, malaise, or fussiness. The differential diagnosis of these complaints is very broad.

**Anemia**

Anemia is a common consequence of malaria, and may be confused with anemia caused by hookworm, TB, bleeding lesions of the gastrointestinal tract (including lesions caused by OIs), ADR to zidovudine, recent obstetrical hemorrhage, and other entities. Anemia is commonly multifactorial. Of note is that malaria-related anemia may continue to progress, and erythropoiesis may be suppressed for days to weeks even after effective clearance of malaria parasitemia. Hence, continued decline in hemoglobin after malaria treatment does not rule out malaria as the primary cause of a patient's anemia.\(^{49,50}\)

**Signs and Symptoms of Severe Malaria**

**Seizures, Impaired Consciousness, Coma**

The clinical presentation of cerebral malaria overlaps with that of toxoplasomic and viral encephalitis, bacterial and cryptococcal meningitis, meningeal TB, and malignancy (e.g., primary central nervous system lymphoma).\(^5^1\) In pregnant women, cerebral malaria may be mistaken for severe pre-eclampsia or eclampsia.\(^5^2\) Altered mentation could also represent an ADR to efavirenz or other medications.

**Hypoglycemia**

Severe malaria is commonly accompanied by hypoglycemia, which may be exacerbated by quinine therapy.\(^5^3\) Hypoglycemia is also a common complication of sepsis in infants and in severely malnourished children.\(^5^4,5^5\)

**Pulmonary Edema**

Acute pulmonary edema caused by malaria may be confused with that provoked by cardiac failure in the setting of myocardial infarction or other cardiac disease.

**Respiratory Distress**

Respiratory distress caused by severe malaria (associated, for example, with metabolic acidosis) is easily confused with that caused by pulmonary infection, cardiac disease, or stavudine-induced metabolic acidosis.

**Lactic Acidosis**

The lactic acidosis that is common in severe malaria may be mistaken for an ADR to certain ARVs, especially stavudine or didanosine.

**Jaundice, Hepatomegaly, Transaminase Elevations, Abdominal Pain, Nausea, Vomiting, Diarrhea**

Severe malaria may present with jaundice, hepatomegaly (enlargement of the liver), moderate transaminase elevations, and/or significant abdominal pain and other gastrointestinal symptoms. The differential diagnosis of these signs and symptoms is very broad, and includes viral or drug-induced hepatitis (e.g., nevirapine hepatitis or stavudine steatohepatitis), cholelithiasis, pancreatitis (including drug-induced pancreatitis), cholangitis, and many other AIDS-related and other entities.

**Severe Anemia**

Severe anemia is a common complication of severe malaria. Notes on the differential diagnosis are given above.

**Intravascular Hemolysis with Hemoglobinuria**

Once thought to be a complication of severe malaria ("blackwater fever"), this particular manifestation of severe malaria is now thought to be an adverse effect of quinine or halofantrine therapy.\(^1\) In patients on indinavir, the combination of dark red urine and flank pain may suggest drug-related nephrolithiasis.

</table>

**Thrombocytopenia**

Severe malaria may be accompanied by thrombocytopenia, with or without clinical bleeding. Malaria, as noted above, is often accompanied by anemia as well, and may occasionally cause leukopenia (leukemoid reactions have also been observed). Several
OIs are also associated with bone marrow suppression; examples include atypical mycobacterial infections and visceral leishmaniasis.

Signs of Asymptomatic Malaria Parasitemia

Anemia is the most common sign of asymptomatic malaria parasitemia. It is particularly common in pregnancy. If untreated, the progressive anemia caused by asymptomatic malaria parasitemia leads to diminished work capacity and elevated risk of infant low birth weight and/or maternal mortality. Anemia in general is considered to be a risk factor for AIDS-related disease progression and mortality. However, as noted above, the differential diagnosis of anemia in the HIV-positive person is quite broad.

Laboratory vs. Clinical Diagnosis of Malaria

Although malaria is commonly diagnosed purely on the basis of clinical signs and symptoms, this approach is unreliable even in patients without HIV infection. Table 3 summarizes the findings of selected studies of the sensitivity and specificity of clinical malaria diagnosis in both adults and children. Although we are not aware of any studies that have addressed the sensitivity or specificity of clinical diagnosis of malaria in HIV-positive persons, the inclusion of OIs, ARV-related ADRs, and IRIS in the differential is likely to render clinical diagnosis of malaria even less accurate in this setting. Both overdiagnosis and underdiagnosis of malaria are hazardous in HIV-positive patients. Overdiagnosis may increase the risk of adverse reactions to antimalarial drugs, drug-drug interactions involving antimalarials and ARVs, and morbidity and/or mortality caused by failure to diagnose and treat the true cause of symptoms. Underdiagnosis may lead to preventable morbidity and/or mortality from severe malaria and/or progressive anemia caused by asymptomatic parasitemia.

The current gold standard for diagnosis of malaria is inspection of a stained capillary blood smear by microscopy. This procedure, as performed under normal field conditions, is currently estimated to be approximately 70% sensitive and 65% specific for the diagnosis of malaria in children under five in sub-Saharan Africa, and permits both speciation of *Plasmodium* and quantification of parasitemia. However, many smaller health facilities operate without laboratories, and even in larger health facilities, microscopy may not be available at night, on weekends, or when limited by shortages of laboratory personnel, reagents, or equipment.

In response to the shortcomings of the existing network of laboratory facilities in malaria-endemic areas, several different types of rapid malaria diagnostic tests are increasingly being used. The advantages and disadvantages of the tests vary by test type, but in general, all of the tests have the advantage of being rapid and relatively simple to perform (as compared to microscopy). Important disadvantages (differing by test) include high cost compared to microscopy (though the difference in cost may be offset by cost savings resulting from decreased wastage of antimalarial drugs), limited capacity to speciate or quantify the infecting *Plasmodium* (particularly if not *P. falciparum*), propensity to yield false-positive results for weeks after clearance of infection (in the case of tests based on histidine-rich protein 2 [HRP-2] antigen), and the need for a “cold chain” of transport and storage. Depending on the test method, the sensitivity of rapid tests for diagnosis of symptomatic *P. falciparum* malaria in residents of endemic regions is thought to range from 62.7% to 92.1%, and the specificity from 98.4% to 99.6%, as compared to conventional microscopy performed under research conditions. A recent head-to-head comparison of two rapid tests based, respectively, on detection of HRP-2 and
plasmodium lactate dehydrogenase (pLDH) antigens, concluded that the HRP-2 test had the higher sensitivity (92% vs. 85%), while the pLDH had the higher specificity (100% vs. 93%); the latter difference was likely the result of more rapid clearance of pLDH from blood after successful antimalarial treatment. Further comparison of the performance of the two test types in settings with different levels of malaria transmission revealed that while the positive predictive values of both tests were consistently high (93% for HRP-2, 98% for pLDH), the negative predictive value of pLDH (but not of HRP-2) dropped to only 54% where transmission intensity was high.

In settings without regular access to microscopy, some national guidelines now recommend that the decision to treat for malaria be made on the basis of clinical impression and rapid-test results alone, but that a malaria smear be prepared for later examination elsewhere in order to permit speciation of parasites and longitudinal assessment of response to treatment.

Because the potential causes of malaria-like signs and symptoms are myriad in HIV-positive individuals, the World Health Organization (WHO) now recommends that, whenever possible, malaria infection be confirmed by laboratory testing before treatment of HIV-positive patients. This recommendation differs sharply from the standard Integrated Management of Childhood Illness (IMCI) and Integrated Management of Adolescent and Adult Illness (IMAI) recommendation that all febrile children, adolescents, and adults with a “high” risk of malaria be treated presumptively with antimalarials. It also conflicts with guidelines for many community-based malaria treatment programs, which recommend presumptive treatment with antimalarials for a range of acute symptoms (not always limited to fever).

Where there is no access to clinician evaluation or laboratory diagnosis, presumptive antimalarial treatment by a community-based health worker—with prompt referral of patients who fail to respond to first-line therapy—may indeed be the best course, and no conflict between disparate guidelines may exist at the practical level. However, where adequate capacity exists and is accessible to the HIV-positive patient, health-facility-based diagnosis and management is preferable. This is of particular importance in HIV-positive patients who receive cotrimoxazole (CTX) prophylaxis and use insecticide-treated bed nets, as these interventions reduce malaria risk dramatically (especially if combined), thus increasing the likelihood that febrile episodes will not be the result of acute malaria.

**TREATMENT OF MALARIA**

In theory, the correct regimen for treatment of malaria depends on the severity of the disease, the responsible *Plasmodium* species, the patient's other current medications and comorbidities, and local patterns of antimalarial drug resistance. In practice, the most effective available antimalarial regimen is often the best choice, regardless of theoretical considerations. National guidelines for first-line, second-line, and third-line antimalarial regimens vary broadly and revisions are frequent. Hence, we will present general recommendations for the choice of antimalarials for patients in specific circumstances rather than specific drug choices. These recommendations are based on our interpretation of the existing literature, not on formal clinical trials (except where indicated).

**Plasmodium falciparum**

*Asymptomatic HIV Infection without Comorbidity or Chronic Medications*

The HIV-positive patient who is not taking ARVs, CTX, TB treatment regimens, or other chronic medications, and who is not pregnant, can be treated with the standard national first-line regimen, assuming that it is known to be effective
(i.e., likelihood of response is not limited by drug resistance). If the national first-line regimen is comprised of only a single agent (monotherapy), or if it is known to have a substantial failure rate, an alternative first line should be defined for HIV-positive persons because of their increased risk of treatment failure, and clinicians should advocate for revision of malaria treatment guidelines for the population as a whole.\textsuperscript{12,13}

**Patients on Prophylactic CTX**

There is known cross-resistance between CTX and sulfadoxine-pyrimethamine (SP), and increased malaria resistance to SP may occur where CTX is widely used.\textsuperscript{75,76} Co-administration of CTX and SP has been associated with elevated risk of severe cutaneous adverse reactions (SCAR), such as Stevens-Johnson syndrome (SJS).\textsuperscript{77} HIV-positive persons on CTX prophylaxis should not receive SP, or SP-based combination regimens, if better options are available.

**Patients on Antiretroviral Therapy and/or TB Treatment**

Patients on combination antiretroviral therapy (ART) or TB treatment may be at risk for drug-drug interactions; there is also the risk of diagnostic confusion when a patient receives antimalarials and ARVs that share overlapping ADR profiles. However, few published data are available to describe the pharmacodynamics or safety profile of antimalarial medications when given in combination with ART, or to describe the pharmacodynamics of antimalarials in the AIDS patient with severe malnutrition or wasting.

**Drug-drug interactions:** Primarily because of their effects on cytochrome P-450-mediated drug metabolism, various ARVs and anti-TB drugs (including most protease inhibitors [PIs], most non-nucleoside reverse transcriptase inhibitors [NNRTIs], and rifampin) are likely to increase or decrease clearance of quinine and halofantrine; these combinations should therefore be avoided.\textsuperscript{78,79} Co-administration of rifampin and quinine has resulted in markedly increased antimalarial treatment failure rates because of rifampin-induced reductions in quinine levels.\textsuperscript{79} Co-administration of efavirenz, artesunate, and amodiaquine has been associated with defective metabolism of amodiaquine in vitro and hepatotoxicity in vivo; in vitro studies suggest that co-administration of amodiaquine with saquinavir, lopinavir, and tipranavir is likely to yield similar results.\textsuperscript{80,81} There is controversy about the co-administration of PIs, NNRTIs, and lumefantrine; the manufacturer of lumefantrine and some reviewers have concluded that the combination should be avoided or be given only “with caution.” Other reviewers have concluded that careful studies have refuted these concerns.\textsuperscript{1,25,78} One pharmacokinetic study in healthy volunteers given ritonavir, lopinavir, and artemether-lumefantrine observed twofold elevation of lumefantrine levels without clinical toxicity.\textsuperscript{82} Early data also describe elevated risk of mortality in HIV-positive patients on zidovudine who were given high-dose pyrimethamine; the manufacturer continues to recommend against this combination.\textsuperscript{83} Finally, there was a high observed incidence of neutropenia (45%) in HIV-positive Ugandan children given the combination of artemether plus amodiaquine, often in combination with zidovudine and/or CTX.\textsuperscript{84} In general, published estimates of the incidence of drug-drug interactions with co-administration of ARVs and antimalarials are scarce. The Liverpool HIV Pharmacology Group maintains an online resource (http://www.hiv-druginteractions.org) that describes important drug-drug interactions involving ARVs and other medications commonly used in HIV care.\textsuperscript{78}

**Overlapping toxicities:** Both nevirapine and SP can cause SCAR, including SJS and toxic epidermal necrolysis. Because of the long half-life of
some ARV agents are active against *Plasmodium falciparum* and other species either in vivo or in vitro. Ritonavir, saquinavir, and lopinavir have been observed to have particularly potent antimalarial effects, but the clinical significance of these findings is as yet undefined.87

**The Pregnant HIV-Positive Patient**

The pregnant HIV-positive patient with symptomatic malaria may be treated in the same manner as the nonpregnant HIV-positive patient, except that medication choices during pregnancy—particularly the first trimester—are restricted by the paucity of available data on teratogenic effects of antimalarials. This issue has been recently reviewed.88 Chloroquine is considered safe in all trimesters but is largely ineffective due to widespread resistance. Quinine is also considered safe in all trimesters; the regimen of choice for acute malaria in the first trimester is now quinine + clindamycin, with artesunate + clindamycin as the second line. During the second and third trimesters, SP, mefloquine, clindamycin, and the artemisinins are also considered safe. The regimen of choice in the second and third trimesters is artemisinin-based combination therapy or artesunate + clindamycin; quinine + clindamycin is the second-line regimen. For severe malaria in pregnancy, intravenous artesunate + clindamycin is the preferred regimen (with quinine + clindamycin as a second choice).25 However, data on the pharmacodynamics of antimalarials in pregnancy are scarce.89 AIDS treatment programs should advocate for the clear definition of appropriate first- and second-line antimalarials for HIV-positive pregnant women.

The pregnant HIV-positive patient who is taking intermittent preventive treatment for malaria should not receive an SP-based regimen for the treatment of acute malaria sooner than one month after the last dose of preventive SP, unless better options do not exist.
*Plasmodium vivax*, *ovale*, *malariae*

The non-*falciparum* plasmodia are generally treated with a combination of chloroquine (to eradicate blood-stage parasites) and primaquine (to eradicate hypnozoites), except where drug resistance has developed. In the presence of chloroquine resistance, local first-line regimens vary, but may include artemisinin-based combinations, mefloquine, amodiaquine, or others.

**Chloroquine**

Thus far, we have been unable to locate reports of significant adverse drug-drug interactions involving chloroquine and ARVs, although theoretical concerns exist regarding interactions with ritonavir.\(^9\) Interestingly, chloroquine has been observed to inhibit HIV replication in vitro; this effect is enhanced in the presence of indinavir, ritonavir, and saquinavir.\(^9\) However, the clinical significance of chloroquine’s anti-HIV activity is as yet undefined.

**Primaquine**

Primaquine is contraindicated in pregnancy and in people with G6PD enzyme deficiency. We have not yet encountered reports of drug-drug interactions involving primaquine and ARVs. Primaquine has been used successfully (in combination with clindamycin) for treatment of *Pneumocystis* pneumonia.

**PREVENTION OF MALARIA IN THE HIV-POSITIVE PERSON**

Multiple methods exist for the prevention of malaria in HIV-positive persons, and may be used singly or in combination.

**Insecticide-Treated Bed Nets**

The insecticide-treated net (ITN) serves as a mechanical barrier to mosquitoes and also repels them through the action of its insecticide. The best nets are now made of fabric to which insecticide has been bonded prior to manufacture; the insecticide is released slowly throughout the life of the net, which does not require retreatment (“dipping”) with insecticide. In children of unknown (likely negative) HIV status living in regions of stable *P. falciparum* transmission, regular use of ITNs has been shown to reduce overall mortality and childhood anemia.\(^9\) In pregnant women, bed nets have been shown to reduce the overall burden of maternal anemia.\(^9\) In Uganda, bed nets provided additional antimalarial benefit in HIV-positive adult patients who were also taking CTX preventively.\(^9\) In HIV-positive Ugandan children, ITN use in combination with CTX prophylaxis was associated with a 97% reduction in malaria incidence.\(^9\) Where community-level coverage of ITNs is high (about 60% of households), households without bed nets derive some protection from malaria because of the insecticidal effect of their neighbors’ nets.\(^9\) In malaria-endemic regions, ITNs should be made available at the lowest possible price (preferably at no cost to the end user) to all HIV-positive persons, their family members, and their neighbors. Mass campaigns appear to be the most efficient means of achieving high levels of bed-net coverage quickly and equitably.\(^9\)

**Cotrimoxazole**

In cohort studies in sub-Saharan Africa, regular use of preventive CTX has been shown to reduce malaria incidence in nonpregnant adults by 72%–99%.\(^9\) CTX prophylaxis alone reduced malaria incidence by 39% in one cohort of HIV-positive Ugandan children (as noted above, the combination of CTX and ITNs was 97% effective in this cohort). No parallel studies have yet been conducted in pregnant women, or in regions where non-*falciparum* species predominate. The durability of CTX protection against malaria is unknown; CTX-resistant malaria has been documented, and
its prevalence is likely to increase in the presence of long-term drug pressure.\textsuperscript{103,104}

**Indoor Residual Spraying**

Indoor residual spraying (IRS) with a variety of insecticides has effectively reduced malaria transmission in a range of settings. For example, IRS progressively reduced malaria parasitemia prevalence in Mozambique during the first five years of implementation; the most dramatic reduction in prevalence was from 65\% to 4\%.\textsuperscript{105}

**Environmental Controls**

Environmental controls have included systematic application of larvicides to mosquito breeding grounds, elimination of standing water, and other methods. Often in combination with IRS, ITNs, and other strategies for transmission reduction, environmental controls have been an aid to the effective control of malaria. Using a combined strategy that included environmental controls, Eritrea succeeded in reducing estimated malaria incidence from 6,000 cases per 100,000 population per year to 1,100 cases per 100,000 between 1998 and 2003.\textsuperscript{106}

**Intermittent Preventive Treatment**

There are two basic types of intermittent preventive treatment (IPT): IPTp (for pregnant women) and IPTi (for young children). IPTp, with two or more treatment doses of an effective antimalarial (usually SP) given after the first trimester of pregnancy, has been shown to reduce maternal anemia and infant low birth weight in multiple prospective studies in regions of sub-Saharan Africa where \textit{P. falciparum} is endemic.\textsuperscript{107-114} IPTi, which involves giving treatment doses of antimalarials (often in conjunction with routine childhood immunizations in children under five), has been shown to reduce the prevalence of childhood anemia and the incidence of malaria episodes in some settings (effect sizes have been variable).\textsuperscript{115}

Neither intervention has yet been evaluated in pregnant women or children taking combination ART and/or preventive CTX, and few studies have been conducted in regions where \textit{P. vivax} transmission predominates. Specific IPTp and IPTi concerns relevant to the HIV-positive pregnant woman or child, on or off ARV or CTX therapy, are discussed below.

**IPTp**

Multiple studies have concluded that two-dose regimens of preventive SP (the most common IPTp regimen) are not as effective in HIV-positive women as in their HIV-negative counterparts, probably because HIV infection confers a higher risk of reinfection after a treatment dose of SP, and because SP is steadily losing efficacy throughout sub-Saharan Africa and other regions.\textsuperscript{114,116} Because HIV infection may also result in maternal anemia and infant low birth weight, measuring the impact of IPTp may be more difficult in these women. Some authors have concluded that the ideal regimen for the HIV-positive pregnant woman would consist of three doses of preventive SP after quickening; others have advocated for monthly administration of SP. Several experts have also observed that new agents are needed to replace SP for the indication of IPTp.\textsuperscript{117} Malaria prevention in the HIV-positive pregnant woman has other complexities beyond the frequency of SP dosing,\textsuperscript{118} including the following:

**IPTp in the pregnant woman on CTX prophylaxis:** CTX alone has been observed to prevent malaria infection in HIV-positive nonpregnant adults. However, no study has yet documented the effect of preventive CTX on incidence of severe maternal anemia, infant low birth weight, placental malaria parasitemia, or other obstetrical outcomes. Because CTX alone is believed to provide protection against malaria, and because the combination
of SP and CTX may result in increased incidence of toxicity, WHO currently recommends that women on CTX prophylaxis not receive preventive SP. However, owing to a lack of coordination between vertically implemented programs, some countries still recommend IPTp with SP (through national malaria control programs) as well as preventive CTX for HIV-positive pregnant women (through national AIDS control programs).

**Overlapping drug toxicities involving SP and nevirapine:** Nevirapine, when taken daily as a component of combination ART, has been associated with a substantial incidence of SCAR, particularly in women with high (greater than 250 cells/mm³) CD4 lymphocyte counts. For example, the incidence of SJS was 3% in one series of Mozambican pregnant women taking triple ART. Both nevirapine-associated and SP-associated SJS may manifest weeks after initiation of therapy, because of the long half-lives of these medications. SJS occurring in the pregnant woman who takes nevirapine daily and has had SP within the past month or so is likely to lead to diagnostic confusion. We know anecdotally that SJS has occurred in women on these regimens, but pharmacovigilance data are as yet inadequate to describe the incidence of this problem. It should be noted that SJS has not been documented in pregnant women who receive single-dose nevirapine to reduce the risk of HIV transmission to the infant.

**Overlapping toxicities involving SP and zidovudine:** The salutary effects of IPTp on maternal hemoglobin may be negated by adverse effects of antenatal zidovudine. One Mozambican study observed a severe anemia incidence of 20% in pregnant women who began daily zidovudine (as part of a triple-ARV regimen) and who had normal hemoglobins at study inception. In contrast, an Indian study failed to note an increased incidence of severe anemia in pregnant women on zidovudine monotherapy. The combination of SP and zidovudine has been previously associated with increased mortality and anemia. Further research is required to characterize the incidence of myelosuppression in HIV-positive women receiving zidovudine and SP concurrently. In the interim, close monitoring of hemoglobin levels—along with regular use of ITNs—is recommended for the pregnant woman who is vulnerable both to malaria and to the adverse effects of zidovudine and SP.

**Role of insecticide-treated bed nets:** ITNs have been shown to reduce maternal anemia, both when used alone and when used in conjunction with SP. Indeed, in one randomized controlled trial of IPTp with SP versus placebo in Mozambican pregnant women whose ITN use was estimated at 90%, SP conferred little advantage over ITN use alone. ITNs also have the advantage of reducing malaria incidence without causing drug-drug interactions. Therefore, pregnant women living in malaria-endemic areas should be urged to use ITNs nightly, and to continue consistent use even after delivery. Nets should be made available at the lowest possible cost to pregnant women and their neighbors. Ideally, HIV-positive women of reproductive age should begin ITN use well before pregnancy occurs.

**IPTp where malaria transmission is unstable or caused by non-*falciparum* species:** The role of IPTp in regions where malaria transmission is unstable, or where *P. falciparum* species are not predominant, has not yet been clarified even for HIV-uninfected women, although one study has now documented the success of IPTp with chloroquine against maternal *P. vivax* malaria.

**IPTi**

As in the case of IPTp, IPTi has largely been studied in HIV-uninfected individuals or in subjects of unknown HIV status; hence, it is unclear whether findings in these populations are generalizable to
the situation of the HIV-positive child. At present, IPTi is primarily implemented in the research setting, but it may become more widespread in the near future. Concerns about IPTi in the HIV-positive infant or young child include the following:

**CTX prophylaxis and IPTi:** As with adults, daily CTX prophylaxis may provide adequate protection against malaria parasitemia in children, although this has not been consistently demonstrated in published trials. It is not clear whether IPTi would confer any additional advantage over CTX alone, or the combination of CTX and ITNs.

Where the IPTi regimen consists of SP (with or without a second agent), children on CTX may be at increased risk of adverse reactions if SP is co-administered (as above). However, there are even fewer data on the incidence of SCAR in HIV-positive children than there are in adults. Where there is a risk that children on CTX may be stigmatized if their parents or guardians decline SP during mass campaigns because of concerns about effectiveness or safety, it may be prudent to devise ways to preserve the confidentiality of HIV-positive or HIV-exposed infants.

**ART and IPTi:** Children who are taking daily combination ART presumably incur risks of adverse reactions and drug-drug interactions similar to those cited above, but incidence data in this age group are sparse.

**IPTi where malaria transmission is unstable or caused by non-*falciparum* species:** The role of IPTi has not yet been clarified where malaria transmission is unstable, or where *P. falciparum* is not the predominant species.

**Malaria Vaccines**

There is as yet no commercially marketed malaria vaccine, although some promising candidate vaccines have now reached the clinical trial stage or are approaching clinical trials.

---

**GAPS IN THE EXISTING EVIDENCE AND GUIDELINES**

People living with HIV comprise an important and vulnerable subgroup among people exposed to malaria infection. Carefully conducted studies have concluded that HIV-positive individuals are at higher risk of malaria infection, higher risk of malaria-related complications, higher risk of anti-malarial treatment failure, and higher risk of adverse effects and drug-drug interactions related to at least some antimalarials, especially if combined with specific ARVs or ARV classes or with rifampin. However, few published studies have evaluated the situation of the HIV-positive person on ART, or the HIV-positive person at risk of *P. vivax* or other non-*falciparum* infection. No studies have described validated algorithms for differential diagnosis in symptomatic HIV-positive persons who are simultaneously at risk for multiple OIs and ADRs whose signs and symptoms overlap those of malaria. Most malaria-prevention studies have focused on populations living where malaria transmission is stable, where *P. falciparum* is the predominant species, and where the status of study participants is unknown or thought to be predominantly negative. The gaps in the existing data are substantial. Our own suggested priorities for future research and policymaking include the following:

1. Description of the effectiveness of daily CTX prophylaxis for the prevention of malaria and its complications (including maternal anemia and infant low birth weight) in pregnant women, people living in regions of unstable malaria transmission, and people living in regions where the predominant species of malaria is not *P. falciparum*.

2. Description of the effectiveness of common first- and second-line ART regimens for the prevention of malaria (asymptomatic, symptomatic, *P. falciparum*, other species) in HIV-positive individuals.
3. Description of the incidence of specific clinical signs and symptoms and the severity of malaria in HIV-positive persons living in a range of malaria-transmission circumstances, and at different levels of immunosuppression. Key questions include the following: What is the actual incidence/prevalence of fever in the immunocompromised individual with acute malaria? What is the actual incidence of severe malaria in patients with WHO stage III or IV HIV disease?

4. Description of the positive and negative predictive values of common rapid malaria tests in HIV-positive persons with varying levels of immunocompromise. (Justification: HIV infection has been associated with increased incidence of false-positive and/or false-negative reactions to other laboratory tests. 126,127)

5. Estimates of the incidence of significant adverse reactions and drug-drug interactions in HIV-positive persons who are given common antimalarials in addition to ART, CTX, and/or anti-TB drugs. Special attention should be given to the safety profile of artemisinin-based combination regimens and common IPTp and IPTi agents.

6. Development of validated algorithms for the diagnosis (and exclusion of the diagnosis) of malaria in HIV-positive persons living in a range of malaria-transmission circumstances, and at different levels of immunosuppression. Of particular importance are guidelines for management of the HIV-positive patient with anemia, fever, or headache when laboratory tests for malaria are negative.

7. Adaptation of WHO staging criteria to include increased malaria incidence and/or severity as indicators of immunosuppression.

8. Adaptation of WHO staging criteria to reflect the apparent effect of acute malaria on CD4 lymphocyte count.

9. Tracking of malaria incidence and severity by HIV treatment programs, just as other important OIs would be tracked.

10. Evaluation of malaria vaccine efficacy in HIV-positive individuals at various disease stages as soon as clinical trials reach the appropriate stage.

GUIDELINES FOR PREVENTION, DIAGNOSIS, AND TREATMENT OF MALARIA IN THE HIV-POSITIVE PERSON

Based on the evidence cited above and our own professional judgment, we offer the following recommendations—which we acknowledge to be somewhat subjective, given the above-mentioned gaps in the evidence base—for prevention, diagnosis, and management of malaria in the HIV-positive person residing where malaria transmission occurs.

Prevention

All HIV-positive adults and children living in regions where malaria is transmitted should be urged to use ITNs regularly. ITNs should be provided as cheaply as possible, preferably without cost to the end user. Where HIV prevalence is high, entire communities or districts should be targeted, not just individuals. ITNs must be made available to HIV-positive persons in a manner that does not stigmatize them; for example, if ITNs are given at no charge to pregnant women who test positive for HIV, equivalent nets should also be given to HIV-uninfected pregnant women and to pregnant women who have not yet been tested for HIV.

All HIV-positive persons should also be instructed in household-level methods of environmental control of malaria, such as installment of window screens and drainage of standing water.

If preventive CTX is medically indicated (based on HIV disease stage, patient drug allergies, etc.) in
a patient who is at risk for malaria, its use should be further encouraged. If it is discontinued (because of ADR or immune reconstitution), the patient should be advised that malaria risk may increase.

Patients who are on preventive CTX should not also receive preventive SP or SP-based combination regimens (in the context of IPTi or IPTp).

National and regional HIV/AIDS control programs should advocate for population-level reduction of malaria transmission (through IRS, larvicides, or other means appropriate for the population in question) where both HIV and malaria are prevalent.

**Diagnosis**

Because so many other clinical conditions (OIs, ADRs, IRIS) may resemble malaria, and because of the importance of avoiding drug-drug interactions and ADRs, presumptive treatment of malaria in the HIV-positive patient should be actively discouraged *where better options are available*. This is particularly important in HIV-positive individuals who use ITNs regularly and receive CTX prophylaxis, as they are at substantially reduced risk of malaria. AIDS programs should ensure that HIV-positive persons have ready access to properly performed microscopy and/or rapid malaria tests. Patients should be counseled to avoid home treatment with antimalarials *where better options exist*. However, if malaria is likely and laboratory testing is unavailable or considered unreliable, antimalarial treatment should *not* be withheld, especially when severe malaria is suspected.

Acute fever should not be the only trigger for clinical suspicion of malaria. The HIV-positive patient at risk for malaria who has acute headache, myalgias, vomiting, or diarrhea; an acute neurologic syndrome (e.g., coma or seizures); pulmonary edema; severe anemia; jaundice; lactic acidosis; or other sign of malaria *even in the absence of fever*, should be evaluated for malaria.

**HIV programs should coordinate with programs advocating community-based (or household-based) presumptive treatment of malaria in order to devise appropriate policies for the management of HIV-positive persons.**

Where HIV seroprevalence is high but microscopy is unavailable, intensified efforts should be made to introduce rapid malaria testing to health facilities and selected community-level health workers.

**Treatment of Malaria**

Clinicians who may be confronted with HIV/malaria coinfection should know which *Plasmodium* species is (or are) transmitted locally, whether the transmission pattern is stable or unstable, and what the local patterns of antimalarial drug resistance are. Similarly, clinicians should be familiar with local and WHO policies for IPTp, IPTi, and diagnosis and treatment of symptomatic malaria infection.

If malaria infection is confirmed or strongly suspected (in the absence of laboratory facilities or in the presence of a negative laboratory result with no other likely cause of symptoms in the patient at high risk for malaria), the most effective available antimalarial should be given in adequate doses as soon as possible. If two or more regimens of roughly equivalent effectiveness are available, the regimen thought safest for the individual (based on pregnancy status, comorbidities, and concurrent medications, including regimens for IPT) should be chosen.

**Related Policy Considerations**

AIDS and malaria programs should collaborate at the national and international levels to define first-, second-, and third-line antimalarial regimens that are appropriate for HIV-positive persons taking daily CTX prophylaxis, daily combination ARVs, and/or rifamycin-based anti-TB regimens. Where
alternatives to the standard regimens are indicated, intensified efforts should be made to make the alternative regimens available to health facilities that care for HIV-positive patients.

Clinicians should be wary of the possibility of simultaneous malaria infection and OI, bacteremia, or other illness.

Like episodes of TB and herpes simplex (infections that occur in both healthy and immunocompromised persons, but with substantially higher incidence in the latter group), episodes of malaria in HIV-positive persons should be reported on the standard forms for the monitoring and evaluation of complications of HIV/AIDS.

Routine monitoring of CD4 lymphocyte counts should be postponed until several weeks after the resolution of an episode of symptomatic malaria. HIV viral load results should be interpreted with caution in the aftermath of a malaria episode.

We encourage AIDS clinicians working in malaria-prone environments to follow the malaria and malaria/HIV literature closely, because the evidence base for these and other recommendations is changing rapidly. Certain existing e-mail list servers may facilitate this.* We also encourage AIDS clinicians to report their own experiences with malaria-HIV coinfection and its treatment, in order to add to the evidence base that is so urgently required to confront the dual pandemics more effectively.

ACKNOWLEDGMENTS

We would like to thank Mark Micek, James Kublin, Juliette Morgan, Carol Hopkins Sibley, Paul Thottingal, Betty Dong, the Seattle Malaria Group, and the leadership of the Mozambican National Malaria Control Program for many thoughtful discussions about these and related issues. Portions of this chapter were adapted from recent papers we co-authored with colleagues (Brentlinger P, Behrens C, Kublin J. Challenges in the prevention, diagnosis, and treatment of malaria in human immunodeficiency virus-infected adults in sub-Saharan Africa. Arch Intern Med. 2007;167(17):1827-1836; and Brentlinger P, Behrens C, Micek M. Challenges in the management of malaria and HIV in pregnancy in sub-Saharan Africa. Lancet Infect Dis. 2006;6:100-111).

SEXUALLY TRANSMITTED INFECTIONS (STIs) are the second most important cause of loss of years of healthy life among women. A 1993 World Bank report estimated that STIs other than HIV accounted for almost 9% of the global disease burden in women aged 15 to 45; they accounted for only 1.5% of the global disease burden in similarly aged men. Globally, the World Health Organization (WHO) estimates that each year, 340 million new cases of curable STIs (gonorrhea, syphilis, chlamydia, and trichomoniasis) occur among sexually active men and women, with the majority of these infections occurring in developing countries. This figure does not include the millions of viral STIs other than HIV, such as herpes simplex virus (HSV), hepatitis B virus (HBV), and human papillomavirus (HPV).

The epidemiology of each STI is different and is shaped by multiple factors, including sexual mixing patterns (which may be moderated by preventive behaviors), the transmissibility of each pathogen, the duration of infectiousness (which is affected by access to effective care), demographics, and social conditions. For example, viral STIs are commonly found irrespective of the level of economic development in a given setting, whereas bacterial STIs remain the second leading cause of disease burden among women of reproductive age in developing countries. For both men and women, STIs are associated with an increased risk of HIV transmission.

The association between HIV and other STIs was first suggested in 1984, with the hypothesis that the presence of some STIs may facilitate the acquisition of HIV infection. Since then, several reviews have documented the association between HIV and both ulcerative and nonulcerative STIs. Overall the evidence points to an important bidirectional, positive relationship between HIV and other STIs. For instance, HSV type 2 (HSV-2) infection, which has become the predominant cause of genital ulcer disease (GUD) in many developing countries, is an important driver of the HIV epidemic in some settings. (For more on this topic, see the chapter entitled “HSV-2 Treatment Interventions to Control HIV: Hope for the Future?”)

STIs can give rise to significant complications. For example, HPV and sexually transmitted HBV infection can result in malignancies of the cervix and liver, respectively. Several STIs can also affect pregnancy outcomes or the health of newborns. For example, untreated early syphilis results in a stillbirth rate of...
25%, as well as a perinatal mortality rate of approximately 20%. Finally, reproductive tract infections can result in infertility, which may have significant social repercussions. The sections that follow detail each major STI, including its diagnosis, treatment, and management considerations for women living with HIV. (Note: HPV and HBV are not included, as they are covered elsewhere in this publication.)

**Cervicitis**

*Chlamydia trachomatis* is the most common bacterial STI worldwide. Cervicitis due to chlamydia generally affects women younger than 25 years of age. Asymptomatic infection is common, leaving women at risk for chlamydia-related morbidity through complications of pelvic inflammatory disease (PID), including chronic pelvic pain, ectopic pregnancy, and infertility. When symptoms of cervicitis exist, they are generally mild and may include an abnormal vaginal discharge or intermenstrual bleeding. Women with cervicitis may have a subclinical upper tract infection and should be assessed for signs of PID. Infection with *C. trachomatis* in men and women may be complicated by conjunctivitis or reactive arthritis. Neonates exposed to the mother’s infected cervix may develop conjunctivitis or pneumonia; thus, a chlamydial etiology should be considered for all infants aged 30 days or less who have conjunctivitis. Risk factors associated with cervicitis include age under 21 years, being unmarried, having more than one sexual partner within three months, having a new sexual partner in the prior three months, having a current partner with an STI, and having a partner who recently used condoms.

**Diagnosis of Cervicitis**

Cervicitis is characterized by the following diagnostic signs: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen, and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os. Vaginal discharge is poorly predictive of cervical infection. Leukorrhea (>10 white blood cells [WBCs] per high-power field on microscopic examination of vaginal fluid) has been associated with chlamydial and gonococcal infection of the cervix; when trichomoniasis is not found, this may be a sensitive indicator of cervical inflammation with a high negative predictive value in the absence of inflammatory vaginitis.

Because microscopy is time consuming and requires special training, its use is generally not recommended at the primary-care level in resource-limited settings. However, if Gram staining can be performed efficiently, as in a referral clinic, it should be performed when women present with vaginal discharge. The most sensitive and specific test available for *C. trachomatis* is nucleic acid amplification testing (NAAT), which can be performed on vaginal, cervical, or urine samples. Other laboratory tests, including culture, direct immunofluorescence, enzyme immunoassay (EIA), and nucleic acid hybridization tests, are available for detection of *C. trachomatis* on endocervical specimens. However, as with NAAT, their use in resource-limited settings is restricted by cost, time, and technical expertise. When laboratory testing is not available, risk assessment should be performed among women presenting with discharge and should be used, along with knowledge of local prevalence of gonorrheal and chlamydial infections, when deciding whether to treat.

**Treatment of Cervicitis**

Coinfection with *C. trachomatis* frequently occurs among patients who have gonococcal infection. Such patients should be presumptively treated for chlamydia. Recommended regimens for chlamydia cervicitis are doxycycline 100 mg orally twice daily for 7 days, or azithromycin 1 g orally in a single
dose. Alternative regimens include erythromycin base 500 mg orally four times a day for 7 days, erythromycin ethylsuccinate 800 mg orally four times a day for 7 days, ofloxacin 300 mg orally twice a day for 7 days, or levofloxacin 500 mg orally once daily for 7 days. Sex partners should be evaluated, tested, and treated if they have had sexual contact with the patient during the 60 days preceding onset of symptoms in the patient or diagnosis of chlamydia. The most recent sex partner should be evaluated and treated, regardless of the time of last sexual contact.

**Chlamydia Infection in Pregnancy**

In pregnant women, chlamydia infection has been associated with a number of adverse outcomes, including increased risk of ectopic pregnancy, preterm delivery, spontaneous abortion, low birth weight, premature rupture of membrane, perinatal mortality, and postpartum endometritis.12-18 In a cohort study, Ryan et al19 showed an increased risk in the incidence of premature rupture of membranes in patients with positive chlamydia cultures who did not receive treatment, as compared with patients with negative chlamydia cultures. Cohen et al20 demonstrated that patients with chlamydia who were successfully treated had a lower risk of premature rupture of membranes than those who were treated but had either persistent or recurrent chlamydia at the end of pregnancy.

Doxycycline (and other tetracyclines), ofloxacin, and levofloxacin are contraindicated in pregnant women. However, data suggest that azithromycin is safe and effective in pregnancy.21-23 Test of cure three weeks after completion of therapy is recommended for all pregnant women, especially considering the potential sequelae in the mother and neonate if infection persists. Erythromycin estolate is contraindicated during pregnancy because of drug-related hepatotoxicity; therefore, only erythromycin base or erythromycin ethylsuccinate should be used.

**Chlamydia Infection in the Setting of HIV Infection**

As previously mentioned, chlamydia infection in pregnancy has been associated with premature rupture of membranes. Although chlamydia infection itself has not been directly associated with an increased risk of perinatal HIV transmission, several studies have demonstrated an increased risk of perinatal transmission with increased duration of ruptured membranes.24-27 Treatment regimens for HIV-positive women are not different from those for HIV-negative women.

**Lymphogranuloma Venereum**

Infection with *C. trachomatis* serotypes L1, L2, and L3 results in the invasive disease lymphogranuloma venereum (LGV). At the site of inoculation, a self-limited papule or genital ulcer may occur. Among heterosexuals, typical presentation of LGV involves unilateral tender inguinal and/or femoral lymphadenopathy (buboes). Rectal exposure results in proctocolitis, with symptoms of mucoid and/or hemorrhagic rectal discharge, anal pain, constipation, fever, and/or tenesmus. Untreated LGV proctocolitis progresses to chronic colorectal fistulas and strictures, and genital lesions may result in genital elephantiasis; either condition may result in secondary bacterial infections. Coinfection with other STIs is not uncommon. LGV is endemic in parts of Africa, Asia, South America, and the Caribbean, though it is rare in industrialized nations. Its epidemiology is not well defined because its clinical presentation overlaps with other causes of genital ulcer disease with bubo formation; therefore, definitive laboratory diagnosis is difficult.28

**Diagnosis of LGV**

Diagnosis of LGV is generally based on clinical features, epidemiology, and the exclusion of other diagnoses. Swabs of ulcers or aspiration of buboes may be tested for *C. trachomatis* by culture, direct
immunofluorescence, or nucleic acid detection where available. However, specific LGV diagnostic testing is not feasible in resource-limited settings, where LGV is most prevalent.

**Treatment of LGV**

Treatment of choice is doxycycline 100 mg orally twice daily for 21 days. Azithromycin 1 g daily for 21 days has been proposed as a therapeutic alternative as well, though data on its efficacy are lacking. Patients with a clinical syndrome consistent with LGV in the appropriate epidemiologic setting should receive treatment in the absence of diagnostic testing. Buboes should be aspirated through healthy skin to prevent the formation of ulcerations. Incision and drainage or excision of nodes may delay healing, and sequelae, such as strictures or fistulae, may require surgery. Erythromycin base 500 mg orally four times daily for 21 days is an alternative regimen and is the treatment of choice for pregnant or lactating women, as tetracyclines are contraindicated in pregnancy. Patients who have had sexual contact with a person with LGV within 60 days before onset of the patient’s symptoms should be examined, tested for urethral or cervical chlamydial infection, and treated with a standard chlamydia regimen, such as azithromycin 1 g single-dose orally or doxycycline 100 mg orally twice a day for 7 days.

**LGV in the Setting of HIV Infection**

Treatment for HIV-positive people with LGV remains the same as for HIV-negative people, although prolonged therapy may be required. Symptoms may resolve more slowly than in those who are HIV negative.

**Gonorrhea**

Gonorrhea is caused by *Neisseria gonorrhoeae*, a Gram-negative diplococcus. Infections in men are typically symptomatic and include a purulent urethral discharge associated with dysuria. Among women, gonorrhea is a major cause of cervicitis, urethritis, and PID. The presence of a gonococcal infection does not usually produce symptoms until complications, such as PID, occur. Other complications from gonorrhea in women include tubal scarring, which is a major cause of infertility and/or ectopic pregnancy. Gonorrhea can also cause accessory gland infection (Skene’s gland, Bartholin’s gland) that is often unilateral. An additional unique manifestation in women is gonococcal perihepatitis (Fitz-Hugh-Curtis syndrome), which is associated with inflammation of the liver capsule. Finally, women can acquire gonorrhea in the anorectal area.

Other manifestations seen in both men and women include pharyngeal infection, conjunctivitis, and disseminated gonococcal disease. Delivery through an infected birth canal can result in ophthalmic and respiratory disease in the newborn. Although the disease’s clinical manifestations are broad, community surveys suggest that there is a substantial pool of asymptomatic *N. gonorrhoeae* among men and women.²⁹,³⁰

**Diagnosis of Gonorrhea**

The diagnosis of gonorrhea can be made by several laboratory methods, including the following:

- Gram stain on a smear of genital discharge
- Culture on selective media
- Nonamplified tests, such as EIA, DNA probe, or direct fluorescent antibody (DFA)
- Amplified tests, such as polymerase chain reaction (PCR) or ligase chain reaction (LCR)

**Treatment of Gonorrhea**

It is generally accepted that the treatment for gonorrhea should be safe, highly effective, single dose, and affordable. Single-dose oral therapies improve compliance; given the large number of patients who
are treated but who get reinfected, safety remains an important concern.

The standard approach to therapy has been to treat both *N. gonorrhoeae* and *C. trachomatis*, because patients are often coinfected. The standard of care in high-income countries has been to use cephalosporins or quinolones. However, the recent widespread emergence of quinolone-resistant *N. gonorrhoeae* (QRNG) infection has resulted in more stringent treatment therapies, thus reducing the options for oral treatment.31

**Gonorrhea in the Setting of HIV Infection**

Little has been published regarding the presentation or response to gonorrhea treatment in patients with HIV disease. There are no data to suggest that the complications of gonorrhea are more common among patients living with HIV than in those who are HIV negative, nor does there appear to be an altered natural history in the setting of HIV-induced immunosuppression.32 As with other inflammatory STIs, the presence of gonorrhea can increase the risk of sexual transmission of HIV. Thus, people with gonorrhea should receive HIV counseling and testing.

**Trichomoniasis**

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis*. Symptoms of trichomoniasis in women include a diffuse, malodorous, yellow-green vaginal discharge with vulvar irritation. However, some women have minimal or no symptoms. Trichomoniasis is a risk factor for development of posthysterectomy cellulitis, tubal infertility, and cervical neoplasia.33-37

Several studies have investigated the prevalence of trichomoniasis among women in Africa. Buvé et al38 performed a cross-section study in four African cities—two with a high prevalence of HIV infection (Kisumu, Kenya, and Ndola, Zambia) and two with a relatively low prevalence of HIV (Cotonou, Benin, and Yaoundé, Cameroon). They found that the prevalence of trichomoniasis was significantly higher in the high-HIV-prevalence cities (29.3% in Kisumu and 34.3% in Ndola) than in Cotonou (3.2%) and Yaoundé (17.6%). Surprisingly, in Ndola, a high prevalence (40%) of trichomoniasis infection was found in women who denied having ever had sex. In a study conducted among 5,221 women in rural areas of eastern Zimbabwe, antibodies to *T. vaginalis* were detected by EIAs, and 516 (9.9%) women were seropositive for *T. vaginalis*, with increasing seroprevalence seen with age among younger women.39

A population-based study of a village population in Tanzania found that *T. vaginalis* vaginitis was the most common reproductive tract infection among participants aged 15 to 44 years (24.7%).40

**Diagnosis of Trichomoniasis**

Diagnosis of vaginal trichomoniasis is usually performed by microscopy of vaginal secretions, requiring immediate evaluation of wet preparation slide for optimal results. Sensitivity of wet prep is in the range of 60%-70%.41 Culture of vaginal secretions is the most sensitive and specific commercially available method of diagnosis. It should be performed when trichomoniasis is suspected yet unconfirmed using microscopy. PCR testing for *T. vaginalis* may be available through commercial laboratories. Several point-of-care diagnostic assays are available for diagnosis of trichomoniasis in women, including OSOM Trichomonas Rapid Test, an immunochromatographic capillary flow dipstick technology, and Affirm VPIII, a nucleic acid probe test that evaluates for *T. vaginalis*, *Gardnerella vaginalis*, and *Candida albicans*. Both tests are performed on vaginal secretions and tend to be more sensitive than wet prep, with a sensitivity greater than 83% and a specificity greater than 97%.42 The results of the OSOM Trichomonas Rapid Test are available in approximately 10 minutes, whereas results of the Affirm VPIII are available within 45 minutes. False
positives may occur in both, particularly in low-prevalence populations.

**Treatment of Trichomoniasis**

Treatment of choice is a single 2 g dose of oral metronidazole or tinidazole. Treatment of sex partners of patients with trichomoniasis is recommended. Patients should be instructed to avoid sex until therapy has been completed and symptoms have resolved for both the patients and partner(s). Although low-level metronidazole resistance has been identified in 2% to 5% of vaginal trichomoniasis cases, high-level resistance is rare. Use of topically applied antimicrobials (such as metronidazole gel) are not recommended, as they are unlikely to achieve therapeutic levels in the urethra or perivaginal glands. Cure rates using metronidazole gel are less than 50%, which is considerably less efficacious for the treatment of trichomoniasis than oral preparations of metronidazole (cure rates of 90%-95%) or tinidazole (86%-100%). In cases of treatment failure with 2 g oral metronidazole, once reinfection has been excluded, options include oral metronidazole 500 mg twice daily for seven days or single-dose tinidazole 2 g. Patients who fail these regimens may be treated with a five-day course of 2 g daily metronidazole or tinidazole.

**Trichomoniasis during Pregnancy and Lactation**

Adverse pregnancy outcomes, such as premature rupture of membranes, preterm delivery, and low birth weight, have been associated with *T. vaginalis* vaginitis. Treatment of vaginal trichomoniasis in pregnancy may prevent respiratory or genital infection of the newborn. However, a reduction in perinatal morbidity with treatment has not been found. Several studies have suggested an association between metronidazole treatment and low birth weight or prematurity, and some recommend deferring therapy in asymptomatic pregnant women until after 37 weeks’ gestation. Treatment with 2 g metronidazole in a single dose may be offered after a discussion with the patient of the potential risks and benefits of treatment. Metronidazole is pregnancy category B, while tinidazole is pregnancy category C; the safety of tinidazole in pregnancy has not been evaluated. For women who are lactating, interruption of breastfeeding is recommended during treatment and for 12 to 24 hours after the last dose if using metronidazole and for three days after the last dose for tinidazole.

**Trichomoniasis in the Setting of HIV Infection**

Patients living with HIV who have trichomoniasis should receive the same treatment regimen as those who are HIV-negative. The incidence, persistence, and recurrence of trichomoniasis in HIV-positive women are not correlated with immune status. A prospective study conducted in women in Mombasa, Kenya, suggested that trichomoniasis was associated with an increased incidence of HIV infection.

**Syphilis**

Syphilis emerged in Europe in the Middle Ages, probably related to the confluence of multiple endemic treponemal infections. Syphilis results from infection by *Treponema pallidum*, a corkscrew-shaped bacteria whose inoculation occurs via microscopic abrasions of the skin or mucous membranes, almost always via sexual contact. A high prevalence of the disease is found in resource-limited settings, as well as among men who have sex with men in urban centers of high-income countries. Notably, the collapse of Eastern Europe’s public-health system following the end of the Soviet Union spurred an epidemic of congenital syphilis.

Primary syphilis typically presents as a solitary chancre, a painless lesion that progresses from a macule to papule to ulcer. The chancre represents the bacteria’s site of entry. Multiple chancres are present in up to 40% of primary syphilis cases. Chancres typically occur on the penis or perineum of men and in the vagina of women, with painless
inguinal lymphadenopathy. Thus, women often are not aware of the disease at this stage. The chancre resolves spontaneously within three to six weeks, signaling the end of the disease’s primary stage.

After hematogenous dissemination, generalized or local skin and mucous membrane eruptions can occur and are often accompanied by generalized lymphadenopathy, signaling the onset of secondary syphilis. Although the rash of secondary syphilis is not specific in appearance, it is notably non-pruritic. Classically, it involves the palms of the hands and soles of the feet.

The host immune response plays a key role in early disease, though it often does not completely eradicate the infection. The subsequent latent period is characterized by a lack of clinical manifestations. Latent syphilis is the presence of positive serology in the absence of clinical disease. Early latent disease is syphilis of less than one year in duration, whereas late latent is defined as disease acquired more than one year prior to the diagnosis of latency. One-third of infections will typically resolve, with no evidence of disease and with negative serology. Another third will continue to have positive serology with no signs or symptoms of the disease. The final third will go on to develop tertiary syphilis, which can present with a variety of chronic illnesses, including granulomatous lesions of the skin, as well as cardiovascular and neurological disease.

Diagnosis of Syphilis
No culture is available for syphilis. In primary, secondary, and early congenital syphilis, dark-field examination is the quickest and most direct laboratory method of establishing the diagnosis. Nonetheless, dark-field examination has several disadvantages—namely, it requires a specialized microscope condenser and lens and an experienced microscopist. In addition, it must be read immediately, as motility is important to identify. Given these challenges, the diagnosis is typically established via serologic tests, which fall into two primary categories: nontreponemal and treponeme specific.

Nontreponemal assays include commonly used tests such as the rapid plasma reagin (RPR) and the Venereal Disease Research Laboratory (VDRL) tests and are typically used to screen for past or present syphilis infection. They are also useful in evaluating the efficacy of syphilis therapy, as well as determining the likelihood of reinfection. Any positive nontreponemal test must be confirmed with a treponeme-specific assay, as biologic false-positive reactions can occur for a variety of reasons, including HIV infection, pregnancy, or other spirochete infections. False positives can also occur in individuals with a history of injection drug use.

Treponeme-specific assays are typically used to confirm a syphilis diagnosis in a patient with a reactive nontreponemal assay. Thus, they are used to reduce the likelihood of a biologic false-positive RPR or VDRL test. Commonly used assays include the fluorescent treponemal antibody (FTA) absorption test, *T. pallidum* particle agglutination assay (TPPA), and microhemagglutination assay (MHA-TP), or an IgG EIA.

Treatment of Syphilis
Penicillin remains the drug of choice for treating syphilis at all stages. Doxycycline is an alternative for penicillin-allergic patients. However, there is no alternative to penicillin therapy for pregnant women and people with neurosyphilis. Primary, secondary, and early latent syphilis are generally treated with one dose of penicillin G benzathine (2.4 million units intramuscularly). Patients with late latent disease should be provided three weekly doses of 2.4 million units of intramuscular penicillin G (7.2 million units total). The efficacy of nonpenicillin regimens (e.g., doxycycline and tetracycline) in HIV-positive individuals has not been well studied and must be considered with caution.
Primary syphilis may have a more aggressive presentation in people living with HIV. For example, multiple chancres, which occur in only 25% of primary syphilis cases, appear to be more common in people living with HIV.61

No significant differences have been noted in the progression to secondary or latent syphilis in the setting of HIV disease. However, rapid progression from the primary chancre to gummatous lesions has been observed in some HIV-positive individuals.62 Other potentially early manifestations of tertiary syphilis in HIV-positive individuals include aortitis63 and neurosyphilis, as noted previously.

The diagnosis of syphilis in HIV-positive individuals does not differ significantly from that in HIV-negative individuals. Both nontreponemal and treponemal tests are accurate and reliable for diagnosis and for response to treatment. However, recent studies suggest that patients with HIV may respond less well serologically.59 Thus, titers may decline more slowly than in patients without HIV infection when treated for early syphilis. Given the reports of rapid progression of syphilis in the setting of HIV infection, a cerebrospinal fluid (CSF) evaluation is recommended in patients with syphilis of unknown duration or in cases greater than one year in duration.

Recommended treatment regimens for each stage of syphilis remain the same, regardless of HIV infection status. However, because treatment failures with the current recommended regimens have been reported in HIV-positive patients, close follow-up is necessary for all those who are HIV positive, regardless of the treatment regimen used.59 Finally, recent data suggest that syphilis in HIV-positive individuals can increase serum HIV load, with a resultant decrease in CD4 count; however, these parameters do improve with standard syphilis therapy.64,65

There is no test of cure available for syphilis. Response to therapy is defined as resolution of clinical signs and symptoms (if present) and a two-dilution (i.e., fourfold) decrease in a nontreponemal serologic titer.

**Syphilis in Pregnancy**

Syphilis can be transmitted from the mother to the fetus at any stage of maternal infection, though the risk is higher in mothers with more recently acquired syphilis. It appears that the risk of fetal infection is greatest if disease is acquired late in pregnancy. Children born with congenital syphilis have a wide range of clinical findings, including dermatologic abnormalities, hepatosplenomegaly, osteochondritis, and a variety of central nervous system abnormalities. Most important, pregnancies in women with syphilis may result in stillbirths.

Data on coinfections with syphilis and HIV at the time of pregnancy are limited. Two prospective studies found no clinical differences in presentation, disease course, and response to therapy, though there was a lag in serological improvement after therapy in patients living with HIV.55,56 A retrospective analysis, however, did find a higher treatment failure among HIV-positive pregnant women.57 Currently, there are insufficient data to recommend a specific regimen for HIV-positive pregnant women,58 although some recommend a longer course of treatment for these patients.

**Syphilis in the Setting of HIV Infection**

Although reports are somewhat contradictory, an altered natural history of syphilis has been reported in the setting of HIV disease. For example, an early study noted rapid progression from early syphilis to neurosyphilis in HIV-positive patients, some of whom received appropriate therapy for early syphilis.59 A subsequent study, however, reported no association between HIV stage and syphilis progression or treatment failure.60
Genital Herpes

Both herpes simplex virus 1 and herpes simplex virus 2 (HSV-1 and HSV-2) infect the ano-genital area, with HSV-2 causing most episodes of recurrence. Genital herpes typically presents as prodromal local pruritus and paresthesia, followed by a red macule and vesicles, which subsequently ulcerate. Most patients with genital HSV have undiagnosed disease, only recognizing disease after they have been educated on the spectrum of presentations. Nonetheless, unrecognized HSV infection can cause serious disease in patient contacts, including primary disease, meningitis, erythema multiforme, and neonatal herpes.

The prevalence of HSV-2 is higher in some regions than in the United States. Recent studies suggest that the overall prevalence of HSV-2 in the United States is approximately 17%, somewhat lower than previous studies have suggested. However, HSV-2 prevalence rates among the adult general populations of sub-Saharan Africa range from 30% to 80% in women and from 10% to 50% in men. Likewise, HSV-2 prevalence rates among women in Central and South America range from 20% to 40%, and in low-income Asian countries, from 10% to 30%. Worldwide, HSV-2 seropositivity is uniformly higher in women than in men and increases with age. In general, HSV-2 seroprevalence is high in populations that have a high risk of acquiring other STIs, such as in populations of STI clinic attendees and sex workers. Some studies from African countries report greater than 80% HSV seropositivity among sex workers. In the United States, HSV-2 is the most common cause of genital ulcers.

Diagnosis of Genital Herpes

Genital infections due to HSV typically present as multiple painful ulcers. Primary HSV infection follows an incubation period of two to four days and is often accompanied by painful regional lymphadenopathy. Urethritis can also be present, presenting as dysuria and a clear urethral discharge. Other findings include a sacral radiculopathy and urinary retention. Diagnosis is confirmed by fluorescent antibody staining and culture of swabs. Lower yields on culture occur once the lesions have crusted over.

Treatment of Genital Herpes

Acyclovir, valacyclovir, and famciclovir are all recommended and can shorten the duration of pain, systemic symptoms, and viral shedding in initial HSV infections. Acyclovir, the least expensive option, is taken at a dose of 400 mg orally three times daily. Although famciclovir and valacyclovir have less frequent dosing (see Table 1), they are more expensive. The regimen for HIV-positive individuals is the same as for those who are HIV-negative. There is no consensus about the use of long-term suppressive therapy for HSV in HIV-positive individuals.

Genital Herpes in the Setting of HIV Infection

Genital HSV disease in individuals with advanced HIV infection can be severe, producing disfiguring disease that responds slowly to therapy. These severe ulcerative lesions typically appear in patients with very low CD4 counts. Infection with acyclovir-resistant HSV occurs uncommonly; it is almost exclusively limited to HIV-positive individuals, primarily due to strains that are thymidine-kinase deficient. Therapy with intravenous foscarnet can be used in these situations. Many additional studies have shown an association between prevalent and incident HSV-2 infection and the risk of HIV acquisition. HSV-2 has been associated with high amounts of HIV-1 in plasma and genital secretions, suggesting that HIV replication can be reduced with antiviral therapy directed solely at HSV-2.

</table>
Granuloma Inguinale (Donovanosis)
Granuloma inguinale, also known as donovanosis, typically causes painless genital ulcers that bleed readily to the touch. The etiologic agent is *Calymmatobacterium granulomatis*, a Gram-negative pleomorphic bacterium. However, it has been proposed that *C. granulomatis* should be reclassified with the genus *Klebsiella* based on phylogenetic similarities.73 Donovanosis is typically found in marginalized populations in diverse settings in Africa, South Asia, and New Guinea. Indeed, the largest epidemic was reported in Papua New Guinea; between 1922 and 1952, 10,000 cases were identified in a population of 15,000.74 Although recent data are unavailable, older data suggest that between 1989 and 1990, donovanosis was the second most common cause of GUD (after HSV-2) in Papua New Guinea.75 A donovanosis epidemic emerged in Durban, South Africa, during the late 1980s. In one study conducted there among women presenting with a genital ulcer, Donovan bodies were identified in 16% of the women.76 More recent reports suggest that the epidemic in Durban peaked in 1997.77

The incubation period for donovanosis is poorly defined and has been reported to be as long as 360 days.77 Experimental lesions induced in humans occurred approximately 50 days following inoculation. Thus, 50 days probably represents a more accurate incubation period.78 Manifestations typically begin as a firm papule or subcutaneous nodule that ulcerates. Typically, the nodule evolves into one of four types of disease:

- Ulcer granulomatous, the most common type, appears as beefy, red, nontender ulcers that bleed readily to the touch
- Hypertrophic or verrucous ulcers with an irregular edge; often dry
- Necrotic, foul-smelling deep ulcers.
- Dry, sclerotic, or circular lesions with fibrous and scar tissue

The genital region is affected in 90% of cases, with the remaining occurrences in the inguinal area.

Diagnosis of Donovanosis
The diagnosis is typically made by identifying intracellular Donovan bodies within large mononuclear cells. Tissue for such studies usually comes from smears obtained directly from tissue or biopsies. PCR testing has been used, but is not widely available in resource-limited settings.79

Treatment of Donovanosis
Azithromycin is currently the treatment of choice. The Centers for Disease Control and Prevention (CDC) recommends 1 g weekly for at least three weeks or until all lesions have healed. Other antibiotics that have been used include cotrimoxazole, erythromycin, and ciprofloxacin. The doses of these therapeutic alternatives are noted in Table 1.

Donovanosis in the Setting of HIV Infection
Given the relationship between genital ulcer disease and HIV acquisition, reports have emerged that HIV transmission is increased in the setting of donovanosis. For example, rates of HIV increased dramatically in Durban, South Africa, during the donovanosis outbreak.80 As yet, there is no evidence of a significant bidirectional impact on the natural history of either donovanosis or HIV in the setting of both infections. However, ulcers secondary to donovanosis have been reported to have a longer duration to resolution in HIV-positive individuals,81 and case reports have suggested failure to respond to conventional treatment in Brazil.77 Nonetheless, most authorities recommend no difference in the standard of care in HIV-positive patients diagnosed with granuloma inguinale.
**Chancroid**

Chancroid is an acute infection that presents as deep genital ulcerations accompanied by inguinal adenopathy and buboes. The etiologic agent is *Haemophilus ducreyi*, a Gram-negative coccobacillus. A tender papule may develop five to seven days after infection, followed by progression to the pustular stage. These pustules can rupture two to three days later, forming painful, shallow ulcers with granulomatous bases and purulent exudates. Lesions typically occur on the vulva, cervix, and perianal area of women.

Chancroid frequently coexists with other STIs. It occurs sporadically in high-resource settings, but remains endemic in resource-limited areas. In urban areas, it is often associated with commercial sex work. For example, in a study of female sex workers in Nairobi, the prevalence of genital ulcers ranged from 5% to 25%, and *H. ducreyi* could be cultured from about half the ulcers.

**Diagnosis of Chancroid**

Diagnosis requires special culture media that are not widely available. Even when such diagnostic resources are used, the sensitivity of culture is less than 80%. Thus, the diagnosis is often made by exclusion, assuming that the following criteria are met:

- One or more painful genital ulcers
- No evidence of *T. pallidum* infection by dark-field examination of the ulcer exudate or by a serologic test for syphilis performed at least seven days after the onset of ulcers
- Clinical presentation of genital ulcers and regional lymphadenopathy
- Negative test for HSV on the ulcer exudate

Several DNA-amplification techniques have been developed. However, these require access to specialized laboratories that are often not available in the regions where chancroid is most prevalent.

**Treatment of Chancroid**

Effective treatment of chancroid cures the infection and prevents transmission to others. If buboes are large and painful, they may require drainage by aspiration. Recommended antibiotics include azithromycin 1 g orally in a single dose or ceftriaxone 250 mg intramuscularly (IM) in a single dose. Dosages for alternative therapies are listed in Table 1.

**Chancroid in the Setting of HIV Infection**

The effect of coexisting HIV infection on the natural history of chancroid is unclear. Some data suggest that HIV-positive individuals have increased numbers of genital ulcers, which may not heal as fast as in patients without HIV disease. In addition, chancroid ulcers contain CD4 lymphocytes, which may increase the susceptibility of an individual with chancroid to subsequent infection by HIV. Of further concern, some reports state that single-dose therapy is associated with reduced healing of genital ulcers and persistence of *H. ducreyi* in the lesions in the presence of HIV disease.

**Pelvic Inflammatory Disease**

Pelvic inflammatory disease (PID) refers to a spectrum of inflammatory disorders of the upper genital tract in women. It may involve the uterus, oviducts, and ovaries, as well as neighboring pelvic organs. PID may include any combination of endometritis, salpingitis, oophoritis, tubo-ovarian abscess, perihepatitis, and pelvic peritonitis. Most commonly, PID is caused by an STI, though it may also be caused by medical procedures, pregnancy, or other primary abdominal processes. Etiologic agents include sexually transmitted organisms, especially *N. gonorrhoeae* and *C. trachomatis*; however, vaginal flora—such as anaerobes *G. vaginalis* and *H. influenzae*, enteric Gram-negative rods, and *Streptococcus agalactiae*—have also been associated with PID. In addition, cytomegalovirus (CMV), *Mycoplasma hominis*,

---

*OPPORTUNISTIC INFECTIONS, CANCERS, AND COINFECTIONS*
Diagnosis of PID

Clinical manifestations of PID are varied, making diagnosis difficult. Symptoms suggestive of PID include abdominal pain, dyspareunia, vaginal discharge, menometrorrhagia, dysuria, nausea, and vomiting. All sexually active women presenting with lower abdominal pain should be evaluated for evidence of PID, and routine bimanual and abdominal examination should be conducted for all women with a presumed STI, because women with PID or upper genital tract infection may not complain of lower abdominal pain. Signs of PID on physical examination include adnexal tenderness, cervical motion tenderness, abnormal cervical or vaginal mucopurulent discharge, and fever. Enlargement or induration of one or both fallopian tubes, a tender pelvic mass, and direct or rebound tenderness may also be present. Laboratory tests that support PID diagnosis include the presence of white blood cells on saline microscopy of vaginal secretions, documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*, elevated erythrocyte sedimentation rate, and elevated C-reactive protein. Laparoscopy can be used to aid in diagnosis; however, it will not detect endometritis or subtle inflammation of the fallopian tubes. Its use is also limited by cost and lack of availability. Thus, diagnosis of PID is usually based on clinical findings. Potential long-term morbidities associated with PID include tubal factor infertility, ectopic pregnancy, and chronic pelvic pain.

Many episodes of PID go unrecognized, due to poor provider recognition of its mild and often subtle symptoms. In general, clinicians should maintain a low threshold for the diagnosis of PID and should err on the side of overdiagnosing and treating suspected cases. Delay in diagnosis and treatment of PID is associated with a higher risk of long-term complications, such as infertility or ectopic pregnancy. Sexually active young women and other women at risk for STIs with unexplained
pelvic or lower abdominal pain and either cervical motion tenderness, uterine tenderness, or adnexal tenderness should be empirically treated for PID.31

Treatment of PID

Treatment of PID involves immediate empiric, broad-spectrum antibiotic therapy, which covers the most likely etiologic pathogens. The antibiotic regimen must be effective against *N. gonorrhoeae*, *C. trachomatis*, anaerobic bacteria, facultative Gram-negative rods, and *M. hominis*. Because negative endocervical screening for *N. gonorrhoeae* and *C. trachomatis* does not rule out upper tract disease, treatment regimens must include coverage of these pathogens. Although some have advocated inpatient management for all women with PID, women with mild to moderate disease may receive outpatient therapy. Hospitalization is recommended in the following cases:

- Uncertain diagnosis
- Surgical emergencies, such as appendicitis or ectopic pregnancy
- Suspected pelvic abscess or tubo-ovarian abscess
- Severe illness, nausea and vomiting, or high fever
- Pregnancy
- Inability of the patient to follow or tolerate an outpatient oral regimen
- Failure to respond to outpatient therapy7,43

Oral Treatment may be considered for women with mild to moderate disease. Women who do not respond to oral therapy within 72 hours should be reevaluated to confirm the diagnosis and should be administered parenteral therapy on either an outpatient or inpatient basis. A number of different recommended outpatient oral regimens are available, including the use of single-dose therapy for uncomplicated gonorrhea (i.e., parenteral third-generation cephalosporin, such as ceftriaxone 250 mg IM or cefoxitin 2 g IM in a single dose plus probenecid 1 g orally administered concurrently in a single dose) plus doxycycline 100 mg orally twice a day for 14 days with or without metronidazole 500 mg orally twice a day for 14 days. If use of a parenteral cephalosporin is not feasible, a 14-day course of fluoroquinolone may be substituted if the risk of gonorrhea is low; in such cases, testing for gonorrhea is recommended before initiating therapy.

Parenteral Treatment. When using parenteral treatment, doxycycline may still be given orally due to its excellent bioavailability. Therapy may be changed to an oral regimen 24 hours after clinical improvement to complete a total of 14 days of therapy with doxycycline; many providers add either 14 days of clindamycin or metronidazole when a tubo-ovarian abscess is present. Recommended parenteral regimens are cefotetan disodium 2 g intravenously (IV) every 12 hours; or cefoxitin 2 g IV every 6 hours plus doxycycline 100 mg orally or IV every 12 hours; or clindamycin 900 mg IV every 8 hours may be used with weight-based IV or IM gentamicin every 8 hours. Alternatively, ampicillin/sulbactam 3 g IV every 6 hours plus doxycycline 100 mg orally or IV every 12 hours can be used.

Male sex partners of women with PID should be examined and treated for *N. gonorrhoeae* and *C. trachomatis* if they have had sexual contact with the patient during the 60 days preceding onset of symptoms. All women diagnosed with PID should be offered HIV testing.

**PID in the Setting of HIV Infection**

It is not entirely clear whether the clinical manifestations of PID differ between HIV-positive and HIV-negative women. A case-control study performed in Abidjan, Ivory Coast, among women with PID found that HIV infection was associated with more severe clinical manifestations of
AWARENESS OF HIV TRANSMISSION RISKS) WITH A HEALTH PROMOTION CONTROL GROUP (WHICH Addressed medication adherence, nutrition, and provider interaction skills). AT THE 12-WEEK FOLLOW-UP, WOMEN IN THE WILLOW PROGRAM REPORTED FEWER EPISODES OF UNPROTECTED VAGINAL INTERCOURSE (1.8 EPISODES VS. 2.5; P = .022), WERE LESS LIKELY TO REPORT NEVER USING CONDOMS (OR 0.27; P = .008), AND HAD A LOWER INCIDENCE OF CHLAMYDIA AND GONORRHEA INFECTIONS (OR 0.19; P = .006).110 OTHER POPULATION-BASED INTERVENTIONS HAVE PRIMARILY FOCUSED ON STI TREATMENT AND PREVENTION AS A MEANS OF REDUCING INCIDENT HIV INFECTION. KAMALI ET AL.111 RANDOMIZED ALL ADULTS LIVING IN 18 COMMUNITIES IN MASAKA, UGANDA, TO RECEIVE BEHAVIORAL INTERVENTIONS ALONE, BEHAVIORAL INTERVENTIONS AND SYNDROMIC MANAGEMENT OF STIS, OR ROUTINE GOVERNMENT HEALTH AND COMMUNITY DEVELOPMENT ACTIVITIES. THEY FOUND NO DIFFERENCE IN HIV INCIDENCE AMONG THE GROUPS. INCIDENCE OF HSV-2 WAS LOWEST IN THE BEHAVIORAL INTERVENTION ONLY GROUP, WHEREAS INCIDENCE OF SYPHILIS AND PREVALENCE OF GONORRHEA DECREASED IN THE COMMUNITY DEVELOPMENT ASSISTANCE ARM.

Periodic Presumptive Treatment

Treatment given for presumed infection at regular intervals is known as periodic presumptive treatment. This approach saves the cost of diagnostic tests and reaches a greater proportion of people than treating only those who are symptomatic. To be effective, treatment must be given at a short enough interval to avoid reinfection. Periodic presumptive treatment may be used as a temporary strategy to reduce prevalence of infection while other strategies for establishing preventive services are being implemented. IN UGANDA'S RAKAI DISTRICT, A RANDOMIZED, CONTROLLED, SINGLE-BLINDED TRIAL COMPARED HIV INCIDENCE AMONG 10 COMMUNITY CLUSTERS ASSIGNED TO RECEIVE EITHER THE INTERVENTION (MOTHER TREATMENT WITH AZITHROMYCIN, CIPROFLOXACIN, OR METRONIDAZOLE) OR THE CONTROL (VITAMINS/ANTIHELMINTIC
drugs) every 10 months. At 20 weeks, the prevalence of syphilis and trichomoniasis was lower in the intervention group, but there were no differences in the prevalence of chlamydia and gonorrhea. There was also no difference in new syphilis seroreactivity or reports of urethral discharge, vaginal discharge, or genital ulcers, nor was there a decrease in the incidence of HIV infection. In a subanalysis of the Rakai trial, Gray et al investigated the effect of presumptive STI treatment during pregnancy on the outcomes of maternal-infant STIs (including HIV) and infant outcomes. Reductions in multiple STIs, including T. vaginalis, N. gonorrhoeae, C. trachomatis, and infant ophthalmia, were observed, as were improved infant outcomes, such as reductions in rates of neonatal death, low birth weights, and preterm deliveries. There was no effect on maternal HIV acquisition or perinatal HIV transmission.

**Structural Interventions**

Structural interventions include changes to policies, guidelines, laws, or environmental factors. Several community-level, nonrandomized trials have demonstrated a reduction in STIs due to structural interventions. In the United States, Lonczak et al studied the effects of the Seattle Social Development Project intervention on fifth-grade students. The intervention had multiple components, including teacher training in classroom instruction and management, child social and emotional skills development, and parent training. When the cohort reached 21 years of age, self-reported sexual behavior, pregnancies, births, and STI outcomes were compared with those of a control group. Although the intervention did not have a significant effect on STI diagnosis among the general study population, the African American members of the intervention group experienced a reduced probability of contracting an STI (by self-report) by age 21 years (OR 0.11; P<1). In northern Thailand, Celentano et al compared HIV and STI incidence in cohorts of 19- to 23-year-old male conscripts in 13 military bases from 1991 to 1993 and from 1993 to 1995 to determine the effectiveness of the 100% Condom Program that began in 1991. This public-health strategy consisted of a public awareness campaign promoting the reduction of high-risk sexual practices, such as commercial sex, and motivating condom use during commercial sex. As part of this strategy, free condoms were distributed to sex workers during periodic STI examinations, and universal condom use in commercial sex was promoted during these visits. In addition, commercial sex establishments visited by men treated for STIs were identified in order to enforce compliance with these recommendations. Investigators found a dramatic decline in the rates of STIs, including HIV infection, associated with these activities. For instance, they observed a 10-fold decrease in STI incidence from 1991 to 1995 and a decline in HIV incidence from 2.48 per 100 person-years in 1991-1993 to 0.55 per 100 person-years in 1993-1995.

**Population Screening**

Population screening for chlamydia takes place in several high-income countries, including Sweden, England, and the United States. However, no national screening program has been assessed in a randomized, controlled trial. In the United States, Scholes et al conducted a study among enrollees of a health maintenance organization. In this study, women who were deemed to be at increased risk for chlamydial infection (according to study criteria) were randomly assigned to either a screening group or usual care. At the end of the one-year follow-up, there was a 56% reduction in the incidence of PID associated with chlamydia screening. Similar reductions in the risk of PID linked to chlamydia screening have been demonstrated in Denmark, where home sampling kits were used to obtain vaginal flush samples that were then mailed...
back to the laboratory facility. Outcomes were then compared with standard of care.118

**Vaccination Programs**

Immunization of at-risk populations is a highly effective tool in the control of infectious diseases. The first vaccine to protect against an STI was the hepatitis B vaccine. More recently, in 2006, a vaccine offering high-level protection to previously unexposed women against HPV types 16 and 18 (which both cause cervical cancer) and types 6 and 11 (which both cause genital warts) has been licensed in the United States and in Europe.119-121

Although the availability of both HBV and HPV vaccines is currently limited in resource-limited settings, such vaccines could be a valuable tool in the control of these STIs. A vaccine against HSV-2 has been tested, showing partial effectiveness among women who had never been infected with either HSV-1 or HSV-2.122

**SPECIAL ISSUES**

**Syndromic Management**

Etiologic diagnosis of STIs remains problematic in resource-limited settings, due to a scarcity of cheap and accurate diagnostic tests. Laboratory testing requires time and financial resources, as well as costly equipment, well-trained personnel, and external quality controls. A syndromic approach to the management of STIs in resource-limited settings has been developed and is a core intervention in the WHO strategy for control of STIs in regions where access to diagnostic testing is limited. Syndromic management involves the identification of a group of symptoms and easily recognizable signs (syndromes) and the provision of treatment that covers the most likely and most serious causes of the syndrome through the use of simple flowcharts.7 Syndromic management can be implemented at many levels of health care and is valid and feasible for the treatment of urethral discharge in men and of genital ulcers in men and women.123,124 HSV-2 is emerging as the most common cause of GUD in developing countries; WHO guidelines recommend the incorporation of acyclovir in the syndromic management when more than 30% of genital ulcers are caused by HSV-2.7

Syndromic management does not work as well for the management of vaginal discharge, which is poorly predictive for gonorrheal or chlamydial cervicitis. Attempts to improve the sensitivity and specificity of the algorithm by incorporating risk assessment and/or speculum exam have been unsuccessful.123,125 A study conducted among 726 women in West African countries presenting with vaginal discharge found that the prevalence of *N. gonorrhoeae* was only 1.9% and of *C. trachomatis* only 3.2%. Risk factors previously recommended by WHO were not associated with the presence of cervical infection, with the exception of the number of sex partners in the past three months. When taken together, WHO risk factors had a positive predictive value of only 6.4% for identification of cervical infections in this population.126

The effect of syndromic management on HIV transmission has been studied. Grosskurth et al127 conducted a randomized, controlled trial implementing improved syndromic management of STIs versus standard of care in six communities in Mwanza, Tanzania, and comparing HIV incidence between the groups. The Mwanza study demonstrated a 38% reduction in HIV incidence in the intervention group, with the greatest impact in women aged 15 to 24 and men aged 25 to 34. A reduction in syphilis seroprevalence and a borderline reduction in new syphilis cases and symptomatic urethritis were also observed in the intervention group, though no effect was seen on gonococcal or chlamydial infection among women receiving antenatal care.127,128
Cost of Treatment
Few studies have been done assessing the costs and benefits of treating STIs. Perhaps the most comprehensive review was published in 2006 and served as a systemic review of the costs of treating curable STIs in low- and middle-income countries. This report reviewed 53 primary studies. The median STI treatment cost was US$17.80 per treatment per person. Clinical settings serving symptomatic patients were consistently less expensive than were outreach services. Notably, services using syndromic management protocols had lower costs, and these costs decreased with scale.

SUMMARY

Key Points
- Early treatment for STIs is important. Most standard recommended regimens are effective for people living with HIV.
- Continuous access to improved STI services is likely to have greater impact on HIV transmission than an intermittent mass treatment approach to STI control.
- Affordable, effective screening strategies for cervical cancer, such as visual inspection aided with acetic acid, are sensitive and cost effective.
- Meaningful involvement of women living with HIV is instrumental in facilitating effective responses. This includes healthy living and healthy sexual activity for people living with HIV. More information can be obtained from specific publications, such as those published by the International AIDS Alliance.

Recommendations
- Systematic screening for STIs should be part of clinical evaluations for women living with HIV and should include thorough medical history taking; clinical examination; and, when resources permit, laboratory examination for syphilis, gonococcal, and chlamydial infections.
- HIV-positive women whose sexual partners are infected with STIs should be offered treatment, even if the women are asymptomatic.
- Cervical screening for STIs should be offered more frequently, using the same tests as for HIV-uninfected women.
- Health workers should be made more aware of the importance of screening for STIs in women living with HIV and of the importance of follow-up in special cases, such as the management of syphilis and PID.
- Regular and systematic screening and treatment for syphilis should be an integral part of antenatal care. This is particularly important and cost effective in pregnant women on treatment interventions for the prevention of mother-to-child transmission of HIV. Reagents and treatment to prevent congenital syphilis are cheap and affordable, even in limited-resource settings.
- More research is needed to formulate effective strategies for scaling up the provision of vaccines for the prevention of oncogenic HPV infections to prevent cervical cancer, especially among adolescents and women living with HIV.

CONCLUSION
Although STIs cause substantial morbidity and mortality worldwide, their impact is often unrecognized. Effective diagnostic tests, antibiotics for bacterial and protozoal STIs, suppressive antivirals, and vaccines against HBV and HPV are often not widely available in resource-limited settings. Syndromic management remains the core intervention for individual case management in resource-limited settings where laboratory testing is not available. Inexpensive, accurate, point-of-care tests are vital for the diagnosis of STIs that are undiagnosed or misdiagnosed by syndromic approaches, particularly in women. A public-health approach to the control of STIs is essential.
This approach should include improvement in surveillance, such as monitoring of sexual behavior and implementation of evidence-based strategies.

The prevention and care of STIs in HIV-positive women should be an integral part of comprehensive sexual and reproductive health services provided to women. The control of STIs, even among HIV-positive individuals, is feasible. Policymakers and health-care providers should be made aware of the special requirements of people living with HIV, such as regular screening for STIs and provision of information, counseling, and treatment for STIs. Pregnant women living with HIV should be provided with services for the prevention of mother-to-child transmission of both HIV and syphilis to prevent babies from being saved from HIV infection only to die from preventable congenital syphilis.

Epidemiological data show a high burden of cervical cancer in high-HIV-prevalence settings, and cervical cancer has been designated as an AIDS-defining illness by the Centers for Disease Control and Prevention (CDC). Yet how two sexually transmitted viruses, human papillomavirus (HPV) and HIV, impact morbidity and mortality in coinfected women in resource-limited settings is virtually unknown. For instance, women living with HIV in South Africa typically present with cervical cancer 10 to 15 years earlier (between the ages of 35 to 40) than HIV-negative women, who usually present with this condition in their early 50s.1,2

With increasing access to antiretroviral therapy (ART), women living with HIV in developing countries are expected to live longer, and morbidity and mortality associated with opportunistic infections are expected to decrease. However, the burden of cervical disease is anticipated to increase in populations where Pap smear-screening programs and colposcopy (microscopic visualization of the cervix) are limited.3,4,5 Further, little is known about the epidemiology and pathology of HPV-related cervical disease in HIV-positive women in resource-limited settings.

This review is intended to update primary healthcare providers on the disease process, including the relationships between HPV and cervical cancer and between HPV and HIV; cervical cancer screening; prevention of HPV infection; and diagnosis and treatment of cervical dysplasia in HIV-positive women in resource-limited settings.

Natural Disease Process

HPV and Its Relationship to Cervical Cancer

Human papillomavirus is a DNA virus with more than 100 identified types. Between 30 and 40 types are sexually transmitted through skin-to-skin or mucosa-to-mucosa contact, leading to anogenital infections in both men and women.6

HPV is the etiological agent for cervical cancer and precursor lesions.6 The lifetime risk for HPV infection among sexually active men and women is at least 50%, and 80% of women will have acquired HPV infection by 50 years of age.7 The individual infectious nature of the various HPV types is unknown, but because of their common route of transmission, many HPV types may be transmitted simultaneously during one sexual exposure.5
Early sexual debut and having multiple sex partners increase the risk of HPV infection. Despite their potential danger, most HPV infections are transient; in a study of 608 HIV-negative college women in the United States, 91% of HPV infections cleared within two years. However, some HPV infections do evade the immune system through a complicated cascade of events, leading to a persistent infection. The natural history of cervical dysplasia is a process of gradual change once the HPV genome is integrated into the human epithelial DNA. Persistent infection of the high-risk types of HPV (16, 18, 31, 33, 35, and 45) is a crucial step in the process of cervical dysplastic changes. Worldwide, HPV types 16 and 18 account for most cervical cancers. However, one or more of these oncogenic types can be found in 90% of high-grade intraepithelial precursor lesions. The E6 and E7 proteins of oncogenic HPV types are known to facilitate the degradation of the tumor suppression proteins of p53 and retinoblastoma tumor suppression protein, respectively. With the loss of the suppression of these oncogenes, apoptosis (cell self-destruction) and cell cycle arrest is disrupted. Changes in the epithelium cells occur with the increase of the nucleus-to-cytoplasm ratio. These precursor changes often occur at the transition zone in the cervix, where the squamous epithelium meets the endocervical columnar epithelium.

Factors that increase the risk of persistent HPV infection and cell dysregulation include immune suppression; cigarette smoking; hormonal contraceptive use; and possibly other sexually transmitted infections, such as chlamydia. The development of cervical cancer can be thought of as a four-step process: (1) transmission of an oncogenic HPV type, (2) persistence of the HPV infection, (3) transformation of HPV-infected epithelial cells, and (4) loss of inhibitory cell replication control causing invasion. Interruption of any of these stages can result in prevention of cervical cancer.

Relationship between HPV and HIV
